The recent findings with Rett syndrome raise a number of interesting questions. One relates to the predominance of neurologic symptoms in the clinical examination. MeCP2 is not uniquely expressed in the brain but is found in many other tissues. Nevertheless, symptoms outside of the brain are not a predominant part of the disorder. It appears that the CNS is particularly vulnerable to disruptions of this gene. One possibility is that during brain development alternate transcripts are differentially expressed; spatial and temporal control of gene expression requires a fine balance between activating and repressing stimuli, at both the transcriptional and the epigenetic level. Moreover, the brain tissue may be more susceptible than other tissues to MeCP2 dysfunction because of the postmitotic nature of neurons (204). A similar situation occurs in Huntington chorea, where neurologic symptoms are also the central part of an illness, although the mutated gene is expressed in many tissues.

A second related question concerns the normal developmental trajectory early in life that precedes the development of symptoms. Much longer delays are seen with a number of neurodegenerative disorders where symptoms are not detected until the fourth or fifth decade of life. One explanation put forward is that toxic compounds are slowly produced over time and must accumulate before neuronal damage occurs. Free radicals are examples of toxic compounds implicated in a number of neurodegenerative disorders, including Huntington chorea. Normally, enzymes are present that detoxify free radicals within cells. If these enzymes lose their full functional activity through a mutation or are expressed in smaller amounts with age, the toxins will accumulate over time and eventually interfere with normal neuronal function.

This may be what happens in the brains of Rett syndrome patients. As discussed, the normal function of the MeCP2 protein is to repress transcription of several additional genes. These downstream target genes are only partially known, but it is reasonable to assume that mutations to MeCP2 lead to the inappropriate expression of these genes. MeCP2 has been show to silence several genes, including *BDNF, hairy2A, Dlx5, and Sgk* (197,205–207). It was recently pointed out that MeCP2 appears to play distinct roles in neuronal subclasses. Mice carrying a mutated *MeCP2* allele in the excitatory neuronal lineage developed cortical hyperexcitation and seizures, whereas removal of *MeCP2* in interneurons recapitulated several features of the Rett syndrome, including stereotyped behavior, autonomic, sensory, motor, and social dysfunction. In fact distinct behavioral phenotypes can be ascribed to *MeCP2* removal from specific interneuron subclasses. For example, particular sensorimotor and social deficits were observed when targeting parvalbumin-expressing neurons, whereas seizures and stereotypies arose in mice carrying the mutation in somatostatin-expressing lineage (202,208,209) . *MeCP2* mutant mice were reported to have a genome-wide, length-dependent increase in gene expression, a finding consistent with observations in the brains of humans with Rett syndrome. Apparently long genes can be enriched for neuronal functions and appear to be selectively enriched in the brain, therefore providing some biologic explanation for why the brain is particularly affected by *MeCP2* mutations (210).

It is possible that the products of these genes are themselves toxic, or interfere with the normal signaling pathways that function during this developmental period. Neuroanatomical studies might clarify this hypothesis. The literature contains a single autopsy report (211) showing abnormalities in pyramidal neurons in layers II–III of the cerebral cortex. They had fewer dendrites than normal and many fewer dendritic arborizations.

LISSENCEPHALY

The cerebral cortex is formed of billions of cells that are born during just a few months of embryonic life from a small population of progenitor cells. The cells that are born must differentiate and migrate to reach the appropriate layer of the cortex. However, a number of disorders are caused by mutations in genes whose proteins are required for the orderly progression from neuronal birth, differentiation into appropriate neuronal subtypes, migration, and eventual elaboration of synaptic connections.

Neurogenesis occurs in a region called the ventricular zone, which lies adjacent to the lumen of the neural tube. Although neurogenesis primarily occurs during the development of the brain in utero, some degree of neurogenesis occurs throughout life (212). In the prenatal cerebral cortex, neurons must migrate past layers of earlier born cells to reach their final destinations. Those born at later periods have more

complex migratory routes. Many employ a guidance system composed of radial glial cells (213). The radial glial cells are thought to send a process that spans the developing cortex and serves as scaffolding along which certain neurons migrate. Chemotaxic signals are produced that keep the neuron moving along the radial glial process. When migrating neuron reaches its final destination, other signaling molecules are produced that instruct it to stop migrating, enter the proper layer, and begin to elaborate processes (214).

Disrupted neuronal migration characterizes several human disorders. The most common of these are the lissencephalies, which consist of several distinct syndromes: isolated lissencephaly (ILS), Miller–Dieker syndrome (MDS), and X-linked lissencephaly (215). In each, disrupted neuronal migration is reflected in a smooth cortical surface that lacks the normal pattern of gyri and sulci. In addition, although the cerebral cortex normally has six layers, cortices of affected individuals have only four (Figure 3.3.3.9).

In 1993, a large deletion on chromosome 17 was identified in two patients with MDS. The search then began to clone the gene responsible for the disorder, and it was soon isolated and termed LIS-1 (216). The deletion spans this gene and genes on either side of it and is another example of a contiguous gene syndrome. Large deletions within the LIS-1 account for up to 70% of cases of MDS, and are not shared by individuals with ILS or subcortical band heterotopia (SBH), where smaller deletions are more commonly reported. The absence of several genes is believed to be responsible for the more severe MDS phenotype, which also has numerous congenital abnormalities. Smaller deletions and/or point mutations in the same LIS-1 gene were soon found in other affected individuals. These individuals had the milder form of lissencephaly (ILS).

How does a mutation in LIS-1 cause the observed cortical abnormalities? LIS-1 encodes a regulatory protein that controls the activity of a second protein, termed platelet activating factor (PAF)-acetylhydrolase (217,218). PAF acts as a signaling protein that binds to the surface of neurons. The ensuing cascade of signals is required for the normal migration of neurons (219). LIS-1 is expressed at its highest levels in the developing cortex, consistent with the protein's putative role in signaling. Exactly how mutations in LIS-1 interfere with normal migration is not well understood, although one model suggests a disruption in cytoskeletal proteins that need to rearrange themselves at the growing tip of the migrating neuron (220). Indeed, LIS-1 was shown to organize the cytoskeleton by controlling the interaction between microtubules protein (like tubulin) and the centrosome components, including dynein, dynactin, NUDE and NUDEL, and to regulate mitotic spindle assembly (221–223). Doublecortin (DCX) also interacts with LIS-1 and the two control the operation of dynein (224). In ILS, intragenic deletions and duplications *LIS-1* are present in approximately 14% of patients, along with pathogenic variants of DCX (also implicated in subcortical band heterotopia) and tubulin alpha 1A

(*TUBA1A*) (225,226). The 14-3-3 family of proteins, which is involved in several cellular function including protein transport and cell migration through its binding to NUDEL, has also been correlated with the severity of cortical malformations in MDS (227–231).
FIGURE 3.3.3.9. Lissencephaly. The normal cerebral cortex is a highly organized structure, and its six layers are shown on the left (12,13,55,73,146,192). In contrast, the lissencephalic brain lacks the normal pattern of sulci and gyri, and there are only four layers. (Adapted with permission from Reiner O, Lombroso PJ: Lissencephaly. *J Am Acad Child Adol Psychiatry* 37:231–232, 1998.)

A second disorder that affects neuronal migration also is due to SBH (232). This disorder, also known as X-linked lissencephaly or double cortex, is associated with cognitive deficits and epilepsy. The histologic findings are made of bilateral bands of gray matter consisting of disorganized neurons present in the central white matter between the cortex and ventricular wall. The degree of cognitive disabilities is

directly related to the thickness of the extra neuronal tissue. The gene that causes double cortex encodes the protein DCX (233–235). Mutations in DCX sequence are most common, with very few cases of deletions or duplications reported. Somatic mosaicism in the *DCXI* has been reported recently (236).

Structurally, this protein is homologous to a family of kinases, called calcium calmodulin–dependent kinases. Although its exact role in neuronal migration remains to be clarified, recent studies indicate that it binds to and appears to stabilize cytoskeletal proteins required for the normal movement of neurons (237,238). As previously discussed, neuronal migration occurs through the establishment of specific cell–cell interactions between the migrating neuron and the radial glia cell that, besides its role in maintaining the neuronal progenitors pool in the ventricular zone, also serves as a scaffold for guidance of differentiating neurons. A radial glia–specific role in the onset of SBH has been proposed in mice, based on the observation that absence of a specific class of proteins regulating the actin and microtubule cytoskeleton, termed small Rho GTPases, led to SBH and cobblestone lissencephaly, a condition characterized by abnormal protrusion of migrating neurons beyond the pial surface (239). Interestingly, layering defects have been recently reported in other cognitive disorders that include schizophrenia and autism (240–242).

Over 20% of individuals with lissencephaly have no detectable mutation in *LIS-1*, whereas a similar number of individuals with SBH have no detectable mutation of DCX. It is possible that additional studies will detect novel mutations within these genes; however, mutations of several other genes have been recently reported for SBH (243,244).

GENETIC BASIS OF COMMON CHILD PSYCHIATRIC DISORDERS

Child psychiatry has yet to establish the molecular basis for most of its more common disorders. The reasons for this failure lie beyond the scope of this chapter, but genetic complexity is one culprit. Many of the disorders described in the preceding sections exhibit Mendelian patterns of inheritance, such as the X-linked transmission of Rett and fragile X syndromes; however, pedigree studies of most common child and adolescent mental disorders fail to show such a pattern of vertical transmission across generations. The presence of non-Mendelian patterns of transmission does not necessarily imply that genetic factors are unimportant, only that their role in the transmission and expression of disease phenotypes is complex. Examples include polygenetic transmission, in which a multiplicity of genetic and environmental factors is causative. Height and intelligence are good examples of polygenetic traits and it may be that some forms of childhood-onset anxiety disorders and ADHD will also fall into this category. Interestingly, the alleles that contribute to the vulnerability to

develop these disorders may be common in the population and be seen as normal variants. However, when they act in concert with other vulnerability alleles or with adverse environments, they may lead to the syndrome in question.

Understanding the genetics of complex disorders is relevant to other fields of medicine and important progress has been made in areas such as breast cancer and hypertension (32,128,245,246). Our field is poised to take advantage of their success. If child psychiatric disorders follow a similar course, we can expect that in rare instances single gene mutations will be responsible for common disease phenotypes. Such observations will set the stage for animal studies that will serve a valuable heuristic role in elucidating additional genes and relevant neurobiologic pathways.

CONCLUSION

Advances in genomics, molecular genetics, and developmental neuroscience provide an impressive array of accomplishments as the foundation for a deeper understanding of the biologic bases of some childhood-onset neuropsychiatric disorders. Success in these areas will likely herald success in other rare diseases, such as autism and other pervasive developmental disorders. Therapeutic advances also can be anticipated as pharmaceutical agents are developed that specifically target the molecular and cellular consequences of specific genetic mutations. Perhaps even the promise of gene therapy can be realized for some of the single gene conditions. Nevertheless, the road ahead, particularly for common disorders, will not be an easy one given the complexities involved and the crucial role of the environment in shaping and reshaping the CNS within the constraints of our genetic endowment.

SECTION IV

CLINICAL ASSESSMENT AND NOSOLOGY

CHAPTER 4.1 ■ FORMULATION AND INTEGRATION

SCHUYLER W. HENDERSON AND ANDRÉS MARTIN

A formulation distills a child's and family's nuanced life stories and experiences into a meaningful synopsis (1). Being able to formulate a case effectively is one of the key skills for clinicians working in child and adolescent mental health, but it is not an easy skill to master. A good formulation is more than just a summary: It turns a patient's narrative and all the information derived from examinations, interviews with parents and teachers, and medical and school reports into a coherent story that will help to develop a treatment plan.

THE SHAPE OF A FORMULATION

A formulation is a narrative with a clinical purpose. To achieve this purpose, it must convey relevant signs and symptoms as well as pertinent negatives, reflecting the breadth and detail of the clinical interview without reproducing the entirety of the interview. It must also provide explanatory contexts for these signs and symptoms, including familial, social, educational, and cultural contexts, so that the signs and symptoms are relevant and meaningful. When it accomplishes these tasks, the formulation can then justify diagnoses (or no diagnosis, if warranted) and point the way toward treatment options based on the diagnostic considerations.

The core components of the formulation typically follow a conventional trajectory with common signposts to guide the reader: referral source, identifying information, history of present illness, significant past psychiatric and medical histories, psychosocial contexts including family history and educational history, mental status, diagnostic considerations, and treatment planning (Table 4.1.1). Consistency in the formulation's route through these domains permits clinicians to follow a familiar path while attuned to important details and nuances.

Whether in psychoanalytic case studies or in brief presentations on ward rounds, and across systems—hospitals, clinical, juvenile justice—and countries, the overall route of the formulation usually remains the same. But as noted, the formulation has a clinical purpose, and that purpose may be different in different settings, and the formulation can be adapted: briskly oriented, for example, toward safety and risk assessments in a crisis service, or with a more leisurely exploration of family and interpersonal factors for a psychodynamic psychotherapy.

Within this broad shape, there are two common models that can organize the conceptual backbone of the formulation. These are the *biopsychosocial formulation* and the *Four Ps*.

THE BIOPSYCHOSOCIAL MODEL

As the biologic sciences became increasingly sophisticated and dominant in the 20th century, concerns were raised about the value of nonbiologic factors in the etiology, presentation, and treatment of diseases and disorders. In the face of these changes, Meyer (2) promoted the "psychobiologic" approach and Engel subsequently developed, named, and advocated for the "biopsychosocial" model, describing it as a "way of thinking that enables the physician to act rationally in areas now excluded from a rational approach" (3). Over the past three decades, the biopsychosocial model has become the most common model for formulating a case in mental health circles and has been widely adopted throughout medicine. The fundamental goal of the model is to prevent reductionism, particularly biologic reductionism, by ensuring that psychological and social factors are not excluded (see Table 4.1.2). The biopsychosocial model may appear to be a neutral mediator between the three domains but, quite specifically, it is not neutral: It is intended to oppose biomedical, psychological, and social reductionism. Regardless of anatomical lesions, clear psychological or obvious social etiologies, this model insists that all three domains be accounted for. By doing so, it has been a powerful and successful model for physicians in all fields of medicine.

The *biologic* domain circumscribes neuropsychiatric, genetic, and physiologic issues, focusing on, but not limited to, the functional operations of the brain and what might be directly affecting it. The *psychological* dimension includes an evaluation of the child's psychological make-up, including strengths and vulnerabilities, and offers the opportunity to include psychodynamic principles like defense structures, consciously and unconsciously driven patterns of behavior, responses to trauma and conflict, transferences and countertransferences. The *social* dimension situates the child in their communities, exploring relationships with family and friends, as well as larger collective cultural organizations like schools, religion, socioeconomic class, and ethnicity.

TABLE 4.1.1

CORE COMPONENTS INFORMING A DIAGNOSTIC FORMULATION

Component	Details Can Include:
Source	Patient, collateral information, records
Chief complaint	What brought the patient in
History of present illness	Symptoms, course, severity, triggering events, pertinent negatives
Past psychiatric history	Previous evaluations, therapies, hospitalizations, medications, and treatments; history of aggression or harm toward self or others; substance abuse history
Past medical history	Illnesses, hospitalizations, surgeries, and medications including folk and alternative medicine remedies, etc.
Family psychiatric and medical	Pertinent positives and negatives in the family's psychiatric and medical history, especially substance abuse, suicide, and cardiac history

history	
Social history	Family constellation, peer relations, interactions with the law and social services, and key events such as immigration
Education history	Schools, grades, report cards, special or regular education, changes in schools, suspensions
Developmental history	Mother's pregnancy and labor, delivery, milestones during infancy; stages of motor, cognitive, social, and behavioral development
Psychological testing	IQ, tests of adaptive functioning, speech and language evaluations
Mental status examination	
Assessment	Diagnoses, hypotheses of causality
Plan	Treatment goals and options, other persons or agencies to contact

Advocates for the biopsychosocial model argue convincingly that it is needed because a "broad approach [is] essential to avoid premature closure of our efforts to understand the patient's needs, tunnel vision or an overly narrow approach to treatment" (4). Furthermore, it is particularly useful for psychiatrists, who are in a unique position within medicine to address the biologic, psychological, and social dimensions of the patient (5), and therefore are responsible for being attuned to each.

Nevertheless, critics of the model, also convincingly, note that the biopsychosocial model is "silent as to how to understand those aspects under different conditions and in different circumstances" (6,7). While insisting that medical materialism or psychological and social dogmatism cannot suffice, this model does not guide the clinician how to weigh the relative contributions of each in any given patient. If a child is being bullied and has an aunt who is depressed, and has always been noted to be a worrier, the biopsychosocial model would provide slots for where each of these facts would fit, but no guidance on what needs to be addressed first, what is most important, what treatment should ensue, *etc*. An additional flaw in this regard is that because the model is agnostic about the roles of biology, psychology, and society, those who prefer one particular realm can devote their attention to it while paying lip service to the others in a few short sentences (4). In particular, the tailing "social" domain is often the least explored (8). Virchow said that "medicine is a social science" and although psychiatry has a history of collaborating with sociology (9), the academic and clinical intersections between mental health and other social sciences remain underexplored. This is especially true in regard to children, many of whom present to child and adolescent mental health workers fundamentally due to social concerns, such as impulsivity and hyperactivity in the classroom, conflict with parents, truancy and school refusal, or other externalizing disorders (10), and where the "social" component is nevertheless given short shrift.

TABLE 4.1.2

THE COMPONENTS OF THE BIOPSYCHOSOCIAL MODEL

Biologic	Psychological	Social
Family history	Emotional development	Family constellation
Genetics	Personality structure	Peer relationships
Physical development	Self-esteem	School
Constitution	Insight	Neighborhood
Intelligence	Defenses	Ethnic influences
Temperament	Patterns of behavior	Socioeconomic issues
Medical comorbidities	Patterns of cognition	Culture(s)
	Responses to stressors	Religion(s)
	Coping strategies	

The most worrying critique of the biopsychosocial model is that it does not blend or integrate the three dimensions as much as loosely knit them together through proximity in the formulation. Thus, how the social, biologic, and psychological are integrated is left unanswered (11).

The biopsychosocial model has been a step toward rethinking reductionism and an opportunity for generating hypotheses about multiply determined etiologies, which may lead to improved capacity for further synthesis and understanding (12). It is, nevertheless, not sufficient and barely good enough.

THE FOUR Ps

The Four Ps model is more sophisticated than the biopsychosocial model in that it imposes a chronology and an etiology on the formulation that suggests how and where interventions can and should take place. The Four Ps model organizes the patient's presentation into *Predisposing*, *Precipitating*, *Perpetuating,* and *Protective* factors (Table 4.1.3).

Predisposing factors are the constellation of features that render the child vulnerable to the presenting symptoms. These may include family history, genetics, medical and psychiatric history, and chronic social stressors. By including these factors here, the clinician is arguing that they are directly relevant to the child's current symptoms. *Precipitating* factors identify the current stressors, inciting events, and concurrent illness. *Perpetuating* factors are those that make the suffering endure, such as the severity of the condition, compliance, deficits in coping or exacerbating social circumstances, and unresolved predisposing and precipitating factors. *Protective* factors describe a patient's strengths, resilience, and supports. Although other models, including the biopsychosocial model, can include strengths and resilience, this model explicitly foregrounds it.

TABLE 4.1.3

Examples of Where the Biopsychosocial Model Meets the Four Ps

The "P" Characteristic and Trigger Question	Biologic	Psychological	Social
Predisposing			
Why me?	Genetic loading	Immature defensive structure	Poverty and adversity
Precipitating			
Why now?	Iatrogenic reaction	Recent loss	School stressors
Perpetuating			
Why does it continue?	Poor response to medication	No support at school	Unable to attend therapy sessions because of parents' work schedule
Protective			
What can I rely on?	Family history of treatment response	Insightful	Community and faith as sources of support

The Four Ps can be easily used in conjunction with other models. As a framework, it can also be used to organize a psychodynamic formulation, including *predisposing* vulnerabilities, personality structure, and family and developmental history; *precipitating* trauma or life events; *perpetuating* maladaptive behaviors and resistances; and *protective* facets of the identity. And it can easily be blended with the biopsychosocial model (see Table 4.1.3).

The Four Ps can be used with the Collaborative Problem Solving (CPS) model (13). The CPS model comprehensively assesses cognitive deficits around frustration tolerance, flexibility and problem-solving, and it exemplifies a collaborative approach to the formulation, with caregivers coming together to understand the child and then working with the child to prevent dangerous or aggressive behaviors. As the child is also involved in formulating the plan, the Four Ps provides a concrete way of organizing the different factors that lead to problematic behaviors in a manner comprehensible to staff and patients alike.

The CPS approach expands on the precipitating and perpetuating factors, especially the ones pertaining to the child's learning (including his or her social learning). It then allows the staff to formulate appropriate, testable, and patient-specific interventions based on observed behaviors and analysis of triggers (precipitating events), continued stresses (perpetuating factors), and strengths that can be tapped into (protective factors). This combination of the Four Ps formulation and the CPS model may be particularly apt on inpatient units (14).

Similarly, Havinghurst and Downey (15) propose a "Mindful Formulation." After collecting information, the Mindful Formulation uses a "patterns" worksheet where the child's affective responses, behaviors, and cognitions are collected in four domains: child functioning; parents'/carers'/siblings'/significant other's functioning; relationships with the child and among significant others; and relationships with and among the community. The goal is trying to discern patterns of strength as well as

patterns of weakness and vulnerability and then to use these patterns to flesh out the Four Ps.

Biologic, psychological, and social elements can fall under each category. The limitations of the Four Ps model include the nonstandard format (one does not begin a formulation with "predisposing factors") and an uneasy overlap between categories. There is little consolidation of the many factors except as to how they affect the patient's symptomology, although strength of the model is that it is nevertheless explicit about arranging potentially etiologic factors.

TABLE 4.1.4

THE FOUR PERSPECTIVES

Perspective	Treatment	Problem/Critique	Requirement
Disease			
What a patient *has*	Cure	Medicines can be toxic	Compliance
Dimension			
What a patient *is*	Guide	Guidance can be paternalistic	Location of strength
Behavior			
What a patient *does*	Interrupt	Stopping can be stigmatizing	Will to change
Life story			
What a patient *wants*	Rescript	Interpretations can be hostile	Insight

Adapted from McHugh PR, Slavney PR: *The Perspectives of Psychiatry*. 2nd ed. Baltimore, MD, The Johns Hopkins University Press, 1998.

THE VARIETY OF FORMULATIONS

Tauber writes that in science "observations assume their meanings within a particular context, for facts are not just products of sensation or measurement, as the positivists averred, but rather they reside within a conceptual framework that places the fact into an intelligible picture of the world" (16). A formulation is not a value-neutral format containing dispassionately arranged facts. The choice as to which facts to include and which to reject and the subsequent ordering and presentation of the facts collude to produce a value-laden product. A formulation is thus a condensation of values, informed by the nature of the encounter between the clinician and the patient; practical goals; training and experience; and implicit and explicit ethics. The formulation is not a value-neutral format containing dispassionately arranged facts. Although there is a historical precedent and pragmatic use for the overall shape of the formulation, we ought not to be naive about the theoretical work a formulation performs and how values influence the shape of a formulation.

We turn now to how different types of values influence the formulation.

Location

The shape of a formulation may depend less on the patient's narrative and more on the location of the clinical encounter. As an example, on a crisis service, an excellent trainee with a longstanding interest in psychoanalysis was presenting thoughtful and rich formulations about children with a focus on developmental conflicts with family and peers; although these issues were far from irrelevant, they did not help the team decide what treatment options were required that day or what immediate services we wanted to offer the family. The trainee's formulations were, however, well suited to his long-term therapy cases. With education on how to revise the formulation for the clinical milieu, the trainee was able to provide thoughtful, psychodynamically informed formulations in concert with other observations and information that resulted in our ability to make plans for the families right then and there.

A formulation needs to reflect the imperatives of the system in which the encounter takes place and therefore mirrors clinical priorities. A formulation may focus on the severity and acuity of a patient's symptoms and needs in a crisis service; it may develop a working model of treatment trials and planning in an inpatient unit; it may narrate the gradual blossoming of relationships, defenses, and cathexes (emotional investments) cultivated and analyzed in a psychodynamic treatment. What each clinical milieu values is reflected in how the child's assessment and treatment will be formulated.

Treatment Values

One of the goals of a formulation is to drive a treatment plan (including no treatment, if warranted), and therefore the shape of a formulation will be influenced by treatment options. Depending upon the type of treatment, the clinician will select questions and areas of assessment to explore. A clinician's training, biases, and experiences will naturally influence how questions are asked and what is explored; one of the advantages of learning different types of formulation techniques and perspectives is that it allows the clinician to become aware of his or her own biases, but also allows them to be explicit about their perspective and why it leads to certain treatment options.

Etiologic Values and Pluralism

What causes mental health disorders, maladies, diseases, and problems? What factors conspire to make a child drop out of school or begin to take illicit drugs? Why is this particular child depressed, or that particular child reporting psychotic symptoms? The biopsychosocial and Four Ps models create a great deal of space in which these questions can be answered, and yet they do not *compel* an answer. They do no prognostic work themselves. There has subsequently been a push toward models that are less flimsy and wishy–washy. A goal has been to develop models

that confidently assert etiologic claims (not with arrogant hubris, but based on what we know as clinicians and with respect for what we have learned from our science and our history).

Attempting to provide an alternative to the biopsychosocial and Four Ps models is the *Four Perspectives* (not to be confused with the Four Ps) (Table 4.1.4). The Four Perspectives distinguish mental health conditions based not on the conglomerative biopsychosocial model, but on etiology and treatment options (17). The concept of pluralism, defined by Havens (18) as a process of "refining methods, not mixing them" has deeply informed the Four Perspectives.

The perspectives in this model each come with a treatment paradigm:

- *Disease*, the keystone of the biomedical perspective, is a clinical entity, a pathologic condition with a specific etiology and with a likely prognosis. The treatment for disease involves prevention and cure, by interventions that directly or indirectly affect the pathologic process and/or symptom relief (which may include psychological interventions).
- *Dimensions* are based on vulnerabilities due to a person's position within ranges of psychological domains (such as intellectual disability or temperament). These vulnerabilities are not "cured" but are addressed with guidance.
- *Behaviors*, maladaptive or undesirable goal-directed activities, need to be ameliorated, stopped, or interrupted, through social, psychological, and/or medical means.
- The fourth perspective is *The Life Story*, based on the reconstruction of narratives through talk therapy. Treatment is usually sought due to emotional states of distress and proceeds through interpretation.

This model includes something rarely discussed in formulations and rarely included in psychiatric models: McHugh (19,20) points to the potential adverse effects of each intervention. All medications can be toxic; guidance can be paternalistic; stopping a behavior can be stigmatizing; and interpretations can be hostile. By making the assessment and acknowledgment of potential adverse effects a cornerstone of the formulation, mental health professionals can collaborate more fully with the patient and family in a transparent and compassionate way.

There is another potential category, "requirement," that could be included in a Four Perspectives formulation. The "requirement" is what is needed for the intervention to work. For a biomedical cure to be effective, there must be an assessment of compliance or adherence to treatment. With guidance, there must be identification of developmental potential, which the guidance can support: For example, in working with a patient with intellectual disability, intellectual, vocational, and occupational strengths must be assessed. Changing behavior requires a will to change, whether this is intuitive, as in the case of a boy who wishes to stop smoking marijuana and has moved from precontemplation into contemplation, or

cultivated through a system of positive and negative reinforcement. And for interpretations to be effective, the patient's insight needs to be appraised.

A formulation based on the Four Perspectives would take as its conceptual point of origin a conviction about the patient's presentation, which would remain adaptable within the overall formulation, and which would then guide the formulation toward specific interventions. One advantage of the Four Perspectives is that they make "explicit aspects of reasoning about patients that are often left implicit or vague" (17).

The pluralistic formulation would proceed as the mental health professional ascertains which categories, perspectives, or dimensions best describe the child's condition; the formulation would then explain how the mental health professional engages in appropriate, directed treatment, having assessed the requirements and acknowledged the concerns. For example, biologic approach (the disease model) has a better fit with bipolar disorder, schizophrenia, and Rett syndrome than it does with grief. The behavioral approach, which targets known harmful behaviors, may be best for substance abuse (although, of course, medical interventions directed toward addiction as a disease can be countenanced as supplemental). The *Life Story model* is geared toward understanding and narrativizing stresses and so would be more helpful for bereavement or stagnation in life's journey.

Culture

In addition to living in a world of etiologic pluralism, we live in a world of cultural pluralism. The formulation can integrate the individual with his or her cultural contexts, without which it may not be possible to understand the patient. A cultural formulation itself has several core components: The cultural identity of the individual (including self-identified cultural affiliations, languages spoken, and levels of involvement with cultures of origin and host/local/dominant cultures); cultural explanations of illness (meanings, cultural explanations for symptoms or cause, and idioms to describe illness); cultural adaptations to the environment and stresses (such as specific stresses in the community as well as areas of support in the community, including possible sources of collaboration); and cultural areas of convergence and divergence between the clinician and the individual (21,22). Attending to this allows for culturally valid assessments on the part of the clinician, but can also be essential in formulating subsequent plans that are acceptable to the patient (23). Culture is everywhere, and children are usually exploring it with vigor. Of all the cultures children participate in, few are more important than the culture of childhood itself. A good formulation will include the child's relationship to this rich culture, including the child's interactions with peers and participation in childhood rituals, and his or her engagement with the cultural life of childhood, from television, games, and sports, to movies, books, and social media. Regarding the latter, specific adaptations

of the cultural formulation for children may include a closer look at their sociocultural immersion in social media: where they spend their time, how they communicate, what they communicate, what adults do and do not know about what they are communicating, and stressors they experience in this virtual world.

A Composite Case Is Presented, Followed by a Biopsychosocial Formulation Focusing on *Risk Ractors for Depression*, and a Four Ps Formulation Focusing on *Suicidality*

A 14-year-old girl, Sara, comes to the clinic after trying to swallow a handful of lithium tablets during an argument with her father. She was stopped by her father and then threw the pills on the floor. Her chief complaint when she meets you is that she is depressed and angry. She says she was angry that her father wanted her to go back to her hometown to live with her mother. Her father had become increasingly frustrated that Sara was smoking so much marijuana and failing at school. Sara says that her depressed mood preceded coming to live with her father. She says she has had months of trouble falling asleep because she's ruminating on her day's failures, and then can't wake up because she's exhausted after a long night of tossing and turning. She says she can't concentrate in her new school, which is why she says she leaves school every day to smoke marijuana. She says it helps her focus and relax and is the one time she enjoys being her new friends. She misses being with her old friends. She says that she has no desire to die right now, but that when she gets really upset she thinks about wanting to be gone forever, particularly because her parents would be sorry and would miss her.

Her father adds that she has been irritable for about 2 months since joining him in the city and that she wasn't like this as a little girl. He says that it has been worsening recently as her school performance has worsened. He says that during arguments she has said with increasing vigor that she wishes she weren't alive. He took her to a doctor who prescribed lithium for mood lability, irritability, and depressed symptoms. Neither Sara nor her father report that she has ever had any psychotic episodes or manic symptoms, although she has been anxious at times, just like her mother was. Her father says that he has no psychiatric history but her mother was "moody" and tried to kill herself when he first said he was leaving for the city.

Biopsychosocial Formulation Focused on Risk for a Clinically Significant Depressive Disorder

Sara is a 14-year-old girl with symptoms of depression, including depressed mood and irritability, trouble sleeping, poor concentration, negative ruminations, and a recent interrupted suicide attempt. Biologic risks for a depressive disorder include a family history of mood lability; substance abuse, which may be exacerbating her depression or her performance in school; and lithium toxicity. Psychological factors include ongoing distress over her parents' separation, feeling trapped between them, and school failure. Social factors include decreased supervision now that she has moved to live with her father, distance from her old friends and family, and conflict with new friends at school.

The Four Ps for Suicidality

Sara is a 14-year-old girl with symptoms of depression and a recent suicide attempt. Predisposing factors for suicidality include her mother's history of suicide attempts; Sara's suicidal ideation, expressed as threats during arguments with her father; and having less supervision and being in a new, isolating environment. Precipitating factors include the stresses of moving to a new city, being in a new school, and a fight with her father. Perpetuating factors include insufficient treatment and worsening depressive symptoms. Protective factors include strong social relationships prior to the move, which can be developed, and a willingness to start new treatments.

THE USES OF A FORMULATION

A case formulation is hypothesis generating and iterative, and can change over time depending upon further clinical encounters, new information, and the clinician's evolving understanding of the child. So what purpose does a formulation serve?

A formulation is a way in which the clinician can understand and explain the patient. As proposed by Jaspers' understanding and explaining may be distinct ways of knowing the patient (24). The depth of our understanding of a patient's experience may not explain the etiology of a symptom in a way conducive to treatment, and likewise a model of behavior may not adequately impart the patient's experience of that behavior. Nevertheless, formulating a case allows the clinician to balance his or her understanding of the patient with his or her explanations.

Understanding a patient requires an intersubjective appreciation of the patient's experiences, hopes and concerns, and is acquired through listening, talking, and interacting with the patient (as well as his or her family and others occupying important roles in his or her world). Explanation of a patient's symptoms and conditions itself has two dimensions: the interpretative task, where psychological, sociologic, and neurobiologic theories are used, ideally in an explicit and evidence-based manner, in order to locate the contributing factors; and the explanatory task,

which connects these factors with the patient's experience. Understanding and explanation work in concert.

A formulation is also a mode of communication. The question of its utility then depends upon the audience and the purpose of the communication. Formulations may need to be comprehensible to the clinicians who will treat the child next; clinicians in another discipline; the audiences for discharge summaries (which, for children, can include parents, schools, social service agencies, and, at times, the children themselves); for outside insurance company employees who review or authorize treatment for an insurance company (which frequently includes adult psychiatrists); and for legal purposes.

Consultation letters are another area where the case formulation is essential. It is widely believed that poor communication between healthcare professionals is responsible for many problems. In one worrying study, the authors reviewed 150 assessment letters from psychiatrists at a clinic in Rotherham, UK, and discovered that 94% of them did not include a case formulation (25).

Keely et al. (26) provide a useful guide for how to formulate a case in the context of a consultation letter.

Information

- Explain the purpose of the consultation at the outset.
- Explain the role the consultation letter will take (e.g., what the letter will include, such as historical information, diagnosis, and recommendations for further treatment).

Include an appropriate case formulation with diagnostic rationale and clear plans for follow-up.

As they note, the role of the formulation may be to educate, especially when the consultation is for those outside the field, and so may include references and explanations to educate the various potential audiences of the letter.

This also raises the question of what should not be included in a formulation.

Being able to discreetly convey information about sex, drugs, conflicts with family, and other potentially inflammatory topics is an important skill to develop. The broader issue is that a formulation requires communication skills that are sensitive to ethical and clinical relationships. An ethical formulation includes these values as well as the values of accuracy and veracity; it should convey clinical material in a way that is sensitive to patients, their confidentiality, and their privacy.

CHILDREN AND FORMULATIONS

The models for case formulation have typically been derived from adult psychiatry. Although child and adolescent psychiatry has offered much to adult psychiatry, and

vice versa, the mantra that children are not simply "little adults" is nowhere more true than in the mental health and experience of youngsters.

How do we specifically adapt formulations for children?

1. *Jargon*: The language of the formulations needs to be precise and relevant to the child's life. This means resisting reliance on jargon, with a cautious use of terminologies that might be derived from and more epidemiologically justified in adult populations. For example, children are frequently referred for mental health evaluation, including from other mental health professionals, for "auditory hallucinations," not necessarily because they are having auditory hallucinations but because they have answered "yes" to questions that are, for them, vague and strange, that possibly approximate their experience, or that are answered concretely ("do you hear voices?"). Although the referral may warrant expert evaluation, the subsequent formulation should resist using "auditory hallucination" unless that precise term is clinically warranted, and not, for example, when the child is lying in bed, trying to go to sleep, and spooked by vivid memories of a horror film watched the night before. The language used in the formulation should therefore be effectively descriptive and the use of clinical terms should be age and developmentally appropriate.
2. *The chief complaint*: This is usually a single line or a symptom, but with children who are brought in by adults, it is worth considering assessing two chief complaints: the chief complaint of the adults and the chief complaint of the child (which, it is true, will often be "I don't know").
3. *Explicitly including family and school as separate categories*: Although this might also be good for adult patients (with a focus on employment rather than school), these realms should be explicitly and comprehensively evaluated in children and thus may merit sections of their own, rather than subsections of "social" in a formulation. Stressors in the family and school can reflect a child's symptoms, exacerbate them, or, indeed, be fundamentally etiologic. In fact, there are no situations in which a child's presentation for services does not reflect difficulties in one or both of these realms, whether the child is reacting to stressors, posing challenges to these domains with his or her behavior, or where his or her symptoms are exacerbated by what he or she is experiencing at home or at school.
4. *Development as a separate category versus inclusion of developmental factors in all categories*: Children deserve an assessment of their developmental history that is not cursory. Much of a child mental health professional's diagnosis and treatment planning is predicated on what is typical or atypical and one of the key concerns in developing a treatment plan and making recommendations is how the presenting symptoms will affect subsequent development. Putting development into its own section may seem to foreground development, but it typically permits a cursory glance at development, instead of integrating development into all aspects of the formulation. Including

development explicitly in all the domains of the formulation can be helpful as a yardstick, instead of relying on a gestalt sense of whether hyperactivity or moodiness is deemed excessive, and can also be helpful in justifying interventions, because sometimes typical behaviors coalesce to produce a constellation of symptoms that would be detrimental to a child's developmental trajectory.

5. *Models of development*: A formulation that is not book length cannot run stage by stage through, for example, Freud, Erikson, and Piaget; the formulation requires choices about which models of development are appropriate. In this regard, as well as others, children suffer from the guild frictions and antagonisms. Using or thinking through various paradigms does not necessarily imply allegiance and dogmatism. This is not to say that all models of development are equally accurate, but the capacity to invoke or countenance different models should not be based on professional competition. Although everybody changes over time, children are in a whirlwind of growth and maturation, accumulating language and skills, experimenting with their expanding world, gaining mastery over tasks while being introduced to more complicated ones on a daily basis. This process is not straightforward and may be better viewed as a punctuated evolution than as a smooth and even progression. Nevertheless, a basic appreciation of expected norms can situate the child and alert the clinician to delays and disorders. In light of this, a useful tool for the formulation can be an assessment of the child's tasks in terms of motor, cognitive, and social development, based on models including Piaget's stages of cognitive development and Erikson's tasks. Expressing the child's development in these terms in the formulation will have additional longitudinal value, documenting development just as growth charts map a child's somatic development.
6. *The individual focus of case formulations*: Formulations are typically written about an individual, not, for example, about a family or a social milieu. They therefore have an ideologic bias toward assessing children as individuals. A formulation, however, can recognize that the child may be presenting for services when the primary problem may not be the child's. Children can be the canaries in the coal mine. Profound family stressors may become manifest in the child's behavior, and it is the family stressor that needs to be addressed primarily; similarly, parents may present the healthiest member of their family to services. The formulation of the child needs to be able to accommodate this, not only to prevent the child from getting unnecessary treatment when better treatments could address the situation, but to avoid collusion in a failure to address predisposing and precipitating symptoms.

CONCLUSION

The formulation in child and adolescent psychiatry is an exciting confluence of ideas. The values of child and adolescent mental health professionals come together with the patient's experience to create a narrative about that patient leading to treatment. It is an iterative and adaptive format, able to accommodate different theories and perspectives to explain what is happening to our patients while we strive better to understand them. Despite these variables, the formulation need not be either intimidating or cumbersome. The science of the formulation is its hypothesis-generating format, modifiable with new information, in service of causal explanations. The art of the formulation is not instantaneously pinning down the right diagnosis, but rather providing a thoughtful, sympathetic portrait of a child in the world.

CHAPTER 4.2 ■ CLINICAL ASSESSMENT OF INFANTS AND TODDLERS

WALTER S. GILLIAM, LINDA C. MAYES, AND AMALIA LONDONO TOBON

Why perform infant assessments? It is perhaps easier to state definitively what infant assessments cannot provide. They do not provide a measure of fixed or immutable intelligence, a trajectory for future development, or a window on future adjustment, nor can they typically partial out the various potential causal factors. Results are descriptive, with only limited application for etiologic understanding or detailed prognosticating. Questions such as "How much of this infant's delay comes from his environment, versus how much from his prematurity?" or "What will be the eventual extent of this child's developmental disability?" are not definitively answerable by a developmental assessment. Developmental assessments, however complete and skillfully done, cannot provide sure predictions of long-term outcome or parcel out the complex contributions of endowment, experience, and maturational forces.

Despite the above caveats, assessment of infant development can be highly useful, and in many cases essential to proper clinical treatment. Skillfully done, these assessments can help create a picture of the child's current developmental level and environmental context that can be invaluable to sound clinical decision-making and treatment planning. Essentially, developmental assessment results help provide a lens through which we might be better able to perceive the world from the child's perspective. Indeed, Bagnato and Neisworth (1) have pointed out that the word *assidere* (the Greek origin of *assessment*) literally means "to sit beside," and hence to get to know someone.

Clinical assessment of infants and toddlers is a subspecialty area of clinical practice. Not all psychiatrists, psychologists, pediatricians, and other professionals will possess the training and degree of closely supervised practice necessary to competently and independently conduct such evaluations. Those professionals who do possess these specialized skills typically have acquired them through formal subspecialization near the end of their professional training.

A BRIEF HISTORY OF INFANT DEVELOPMENTAL ASSESSMENT

A brief discussion of the history of infant assessment may provide an illustration of the evolving aims and technologic advances in this field. (A more complete history is provided by Brooks & Weinraub (2) and Wyly (3).)

In the late 19th century, the European scientific community was consumed with a fervor and creativity best characterized by the studies of evolution, theories about the

unconscious mind, and a growing concern for persons with mental illness and intellectual challenges. The science of child development was dominated by single-child case studies—often the children of the scientists. By the early 20th century, a concept of measuring infant capacities grew out of the concern of scientists of the time to find a metric for human intelligence that would permit the creation of criteria for schools for children with intellectual deficiencies (4,5). By the 1920s to 1940s, two basic approaches were used in exploring intellectual development in infants. One approach, the infant IQ model, sought to extend downward the IQ assessment model to children younger than school age, eventually including infants. Overall, "infant IQ tests" were found to be inadequate at meaningfully extending the IQ assessment model into infancy and are now all but extinct in use. A second approach, the gesellian model, sought to create a new model of assessment that began with the newborn and extended upward.

Several aspects of Gesell's work distinguish it from those of his predecessors and contemporaries. First, whereas the infant IQ tradition grew from an interest in identifying deviant patterns of development, Gesell's interest was mostly in documenting normal developmental trends. Second, Gesell's model supported the conceptualization of development occurring simultaneously in many distinct but interrelated domains (6), as opposed to a singular factor of intellectual ability. Third, Gesell's model of developmental maturation supported an understanding of the effects of the child's environment in altering the course of development, as opposed to viewing IQ as a stable and static trait, opening the way for the more transactional and dynamic understanding of developmental processes that would later prevail. Gesell's work was far-reaching, and subsequent researchers, such as Nancy Bayley, relied heavily on the developmental tasks and techniques he pioneered. Bayley applied testing concepts more familiar to the infant IQ model to the assessment techniques developed by Gesell, resulting in two scales of infant development that would later revolutionize and dominate the field of infant assessment.

In the 1940s and 1950s, the science of infant developmental assessment gained greater international attention, through the publishing of the *Griffiths Mental Development Scale* (7) in London. American developmentalists first began to consider seriously the stage theory of Jean Piaget, which clearly favored the view of qualitative, rather than simply quantitative, differences in the abilities of children of various ages. The 1960s and 1970s were breakthrough decades that brought a new wave of infant development tests, more rigorously standardized on larger numbers of infants, with careful testing of interobserver agreement and test–retest reliability. The *Bayley Scales of Infant Development* (BSID) (8) consolidated Bayley's original two scales into one assessment instrument with norms based on a nationally representative sample of infants. The BSID set a new and enduring standard of sophistication for the development and standardization of infant developmental assessment tools. Concomitant interest in newborn capacities and the rapidly

emerging field of newborn sensory perception also led to the development of a number of scales to measure competency in newborns.

The last three decades have led to further psychometric improvements, a renewed interest in diagnostic functionality, and the application of information-processing theory to the study of infant development. Federal mandates for the special education of young children created the need for an arsenal of assessment tools that encompassed all of the qualifying areas of delay, utilized information from both direct assessment of the child and parent report, and facilitated early intervention treatment planning and program accountability. The federal early childhood special education laws also instantiated the notion of a five-factor model of development (Motor [gross and fine], Communication [receptive and expressive], Cognitive, Adaptive or Self-Help, and Personal–Social or Social–Emotional) that has since been replicated in nearly all currently existing developmental measure. Also, a plethora of brief developmental screening instruments also were developed for use by professionals with relatively little training in formal assessment.

INTERVIEWING, OBSERVING, AND SYTNTHESIZING INFORMATION

The developmental assessment of infants involves more than the simple administration of a set of developmental test protocols. Assessments performed in the first 3 years of life require the clinician to function simultaneously as a generalist and a specialist, to blend quiet observation with active probing, to synthesize information from caregivers with that gathered through direct observation of the child, and to be involved in a curious blend of searching for specifically defined responses from a child with inferences based on behavior. This set of skills is indeed important for adequate clinical assessment of children of all ages. However, the need is even greatest for those providing clinical services to these youngest of patients, since development during the early years is the most rapid, context dependent, and intersystemic. (See Table 4.2.1 for a summary of some of the information obtained during an infant assessment.) While interviewing, observation, and synthesis are the skills of medical diagnosis in general, there are unique aspects to each in the process of assessing infants.

Interviewing

Skillful interviewing is central to a complete developmental assessment, since much of the data about infants' daily functioning and their relationships with others come from interviews with the caregivers. Skillful interviewing techniques include letting caregivers begin their story wherever they choose; using directed, information-gathering questions in such a way as to clarify but not disrupt the parents' account;

and listening for affect as much as content. Importantly, nearly every step of the assessment process requires an alliance between clinician and caregiver, since infants usually perform better when they are in the company of familiar adults, and the initial interview between clinician and family is crucial in setting the tone for such an alliance. Moreover, establishing an alliance is central to evaluating infants' interactions with the adults in their world. Indeed, infant assessments are quite compromised when there are no familiar adults available to meet with the clinician and be with the infant. Parenthetically, it is often in cases involving the most severe environmental disturbance that clinicians do not have access to caregivers that are able to describe the infant's history.

Addressing Caregiver Fears Regarding the Assessment

When parents, foster parents, or other caregivers are available, skillful interviewing is also critical in helping parents follow through with the assessment process. Coming for a developmental evaluation or participating in one while their infant is hospitalized is enormously stressful and often frightening for caregivers. Clinicians working with infants and their families need to understand that, regardless of what caregivers have been told about the assessment, caregivers' fears and fantasies about the process are as potent as the facts of the presenting problem. Not uncommonly, caregivers have begun to see the infant as damaged or defective in some way and are afraid and guilty about the effect of their own behavior on the infant. Their fears of what the infant's problems signify may be expressed in many ways. They may anticipate that their infant has a serious developmental disability, such as autism or intellectual disability, or that the infant will have serious emotional difficulties in school, or that they themselves will be, or already are, inadequate caregivers. It is a vulnerable time for caregivers, and clinicians should keep in mind that what seem inconsequential moments and statements to them may be memorable and powerful for many caregivers. Furthermore, the stress of coming for an assessment affects the caregivers' abilities to report about the infant's development. Often, the "facts" start to change as the alliance between caregivers and clinician develops.

TABLE 4.2.1

Some of The Information Obtained During an Infant Assessment

Caregiver Interview	Observation or Formal Evaluation of Child
• Family history • Genetic influences • History of pregnancy, delivery, perinatal period • Developmental history (developmental milestones, previous assessments) • Medical history • Child care and extended family arrangements • Child's psychological role in family	• Physical health, appearance, and growth parameters • Sensory development (vision, hearing, tactile, etc.) • Gross motor development • Fine motor development • Communication development • Receptive communication

- Caregiver perceptions and expectations of child
- Stability of home/family environment
- Family social support systems
- Family functioning, stress, and coping (alcohol and drug abuse, domestic violence, etc.)

Observation of Caregiver and Infant

- Infant's use of caregiver for support and reassurance
- Caregiver's attunement and responsiveness to child's affective state
- Elicitation and receipt of positive interactions
- Security of attachment between caregiver and infant
- Caregiver affective response to child's efforts during assessment

- Expressive communication
- Speech clarity and fluency
- Cognitive problem-solving
- Developing sense of self
- Social relatedness and interest in environment
- Capacity for affect regulation and coping skills
- Emerging mastery motivation
- Capacity for symbolic representation and play

Active Listening

When first interviewed, caregivers may be reluctant to be candid or may not themselves be fully aware of their own perceptions and beliefs about the infant. Open-ended questions, allowing caregivers to begin their story wherever they feel most comfortable, and conveying a nonjudgmental attitude are crucial beginning points in establishing the working alliance. Also, at the risk of stating the obvious, such "interviews" involve considerably more listening than active questioning. Indeed, the type of active listening involved in this type of interview requires the clinician to do much more than passively collect and record requested information, it involves forming numerous connections between "factual" information, observational information (the reactions of the caregivers and their affective responses), and an appreciation of the context of the relationship between the caregiver and the clinician.

Content of the Interview

The important areas to cover in terms of the infant's development are the medical history and major developmental milestones; the history of the mother's pregnancy, delivery, and immediate perinatal period; the number, ages, and health of family members; and how the infant fits in the family's daily life (9). The meaning of the individual child for all caregivers is an important window on the infant's place in the family. Many infants and toddlers attend child care or early intervention programs, and the perception of those teachers, as well as their relationship with the infant's primary caregivers at home, is also important.

More specifically, the interviewer should try to get a picture of the caregivers' perceptions of the infant's level of functioning in several areas. These include motor

development and activity level, speech and communication, problem-solving and play, self-regulation (ease of comforting, need for routines), relationships with others, and level of social responsiveness. Questions about whether or not the pregnancy was planned or came at a good time for the family and what expectations the parents had for the infant provide important information about perceptions, disappointments, and stresses. Similarly, asking the caregivers of whom the infant reminds them or what traits in their infant they like best and least may be useful avenues for learning about how the parents view both the infant's problem and his or her place within their family.

Techniques of Organizing Information

Provence (10) has suggested that a productive method of gathering developmental and family data is to ask the caregivers to describe a day in the life of their child. Provence outlines how this question can be the framework for learning about daily activities, how the infant and caregivers interact throughout the day, and about interactions around mealtime, bedtime, or times of distress. When all major caregivers are present for the interview, this question provides a time for each of them to present descriptions of his or her time with, and perceptions of, the child. Additionally, clinicians may use structured interviews, such as the *Vineland Adaptive Behavior Scales* (11) currently under revision, in order to collect both quantitative developmental data and provide an opportunity to open new areas of clinical discussion. Also, the *Infant-Toddler Developmental Assessment* (IDA) (12), appropriate for infants from birth to 36 months, is particularly useful in providing a schemata for organizing important information from caregiver interviews, medical/developmental records, and behavioral observations.

Implicit in this overview of interviewing is the assumption that such assessments require several sessions. Minimally, one meeting with caregivers, two or more with the child and caregivers together, and another to present the results to the caregivers are necessary. The sessions with the infant also provide an opportunity to gather more interview information, as other questions will occur in the context of the child's behavior and performance. For example, asking whether the child's response to a particular situation within the evaluation context is usual for him or her may open up another area of information from the caregivers. As is likely clear from these suggestions, infant assessment is a process of constantly gathering information, revising impressions, and testing hypotheses—and that requires time.

Observing

Observation is the fundamental skill needed for measuring infants' development. After all, most diagnostic evaluations are based on observation of physical signs

and/or behavioral responses. However, what distinguishes the observational skill necessary for developmental assessment is that it occurs on many levels simultaneously and is perhaps the area in which the developmentalist's dual role as both generalist and specialist is most evident. Moreover, the observational skills inherent in assessments of infants require a blend of free-floating attention bounded by a structure. In other words, while the clinician must be comfortable enough in the setting to attend to whatever occurs, he or she must also have a mental framework by which to organize the observations collected during the session. Such a framework entails at least four broad areas: (a) predominant affective tone of the participants, (b) involvement in the situation (curiosity and interest), (c) use of others (child's use of the caregivers or examiner), and (d) reactions to transitions (initial meetings, end of sessions, and changes in amount of structure).

What to Observe

Clinical observation begins from the very first contact with the caregivers and infant, including the caregiver interview addressed above. Many important observations of the infant and infant–caregiver and familial interactions can be obtained during the course of formal developmental assessment. Benham (13) has provided an elaborated framework for structuring observations of infants and toddlers based on the familiar psychiatric mental status examination. In many cases, however, the formal developmental evaluation alone may not provide sufficient opportunity to observe all of the important behaviors of the infant and caregiver. Infants may behave differently with different caregivers and in varying contexts. For this reason, both naturalistic and structured analog procedures, where the examiner attempts to recreate specific "home-like" scenarios (e.g., a parent requesting the child to clean up the toys), can often be used to gather additional observational data that can be useful for both clinical and research purposes (14). Play-based assessment allows the clinician the opportunity to observe the infant and caregivers in a less structured format than provided by the formal developmental assessment. Also, play observations can be very useful in gaining additional information about the infant's cognitive, symbolic/linguistic, social, and motor development, as well as in assessing internal emotional states and conflicts and the infant's internal dynamic representations of the world (15).

Levels of Observing

Within the four broad areas of observation described earlier, the clinician makes observations continuously on at least three levels. Perhaps the most obvious level is the observations of how the child responds to the structured assessment items administered during formal testing. As already stated above, observations during formal testing should not be confined to whether or not the child passes or fails a

given item, but to how the child approaches the task. The second level of observation during an infant assessment is how the child reacts to the situation apart from the formal testing structure. Does the child approach toys, initiate interactions, refer to the examiner or his caregivers? How does the child react in the beginning of the evaluation versus later, when the situation and the examiner are more familiar? The third observational level is a specific focus on the interactions between caregivers (and other adults) and infant.

The clinician makes these observations throughout the evaluation process and revises hypotheses as both caregivers and infant become familiar with the process. How to interpret the behaviors one observes between caregivers and child in terms of their ongoing relationship is learned partially by experience and requires time to gather many observational points. However, several general areas may provide important descriptive clues. Does the child refer to the caregivers for both help and reassurance? Similarly, does the child show his successes to the caregivers, and do the caregivers respond?

Another important observation for toddlers is whether or not the child leaves his caregivers' immediate company to work with items or explore. For infants, how caregivers hold, feed, and comfort their baby may be windows in the emerging dyadic and familial relationships. A caregiver participates with his or her child during such sessions in varying ways, and the clinician continuously will be assessing qualitative aspects of that participation—how intrusively involved, withdrawn, or comfortably facilitative the caregivers are.

One of the most important lessons when learning how to observe interactions between infants and caregivers is that clinical observations, even when based in a naturalistic setting, may or may not be an adequate reflection of what is typical for that particular family. Adults may appear very different as individuals in their own right, compared to when they are interacting with their children. Also, the assessment context where one's child (and by implication, one's self as a person and as a caregiver) is observed by another is anxiety provoking in varying degrees for all parents, and may profoundly alter their parenting style. Also, it is important that the assessor realize that he or she is also an integral component of the assessment. How does the infant respond to the evaluator? How does the infant use her familiar caregiver to navigate the introduction of the stranger (evaluator) and manage her stranger anxieties? How does the infant warm to the stranger over time? And, how does the evaluator observe her own internal feelings or countertransference regarding the infant, the caregiver, and their relationship?

For very young children, assessing development involves elaborating a more complex view of the child and his or her environment, and at this age, every developmental evaluation must include descriptions of behavior and the qualitative aspects of the child's behavior in the structured setting. For example, *when* the infant first turned to a voice or successfully retrieved a toy in a manner appropriate for age

may be less important than *how* he or she responded to these tasks (with excitement, positive affect, and energy versus slowly, deliberately, and with little affective response). Such qualitative observations are often the best descriptors of those capacities for which we have few standardized assessment techniques but that are absolutely fundamental to fueling the development of motor, language, and problem-solving skills. Through observing how infants do what they do, the clinician gains information about how infants cope with frustration and how they engage the adult world, as well as about their emotional expressiveness, their capacity for persistence and sustained attention, and the level of investment and psychological energy given to their activities.

Synthesizing

Synthesizing the large amount of data obtained from a comprehensive clinical infant assessment can be quite daunting. The clinician must draw upon and synthesize knowledge from child psychiatry, pediatrics, neurology, developmental psychology, speech/language therapy, physical and occupational therapy, and often genetics and endocrinology (16). Increasingly, clinicians evaluating young children need also know about early childhood education programs and early intervention, as well as laws regarding child abuse, neglect, and domestic violence. Knowledge from these diverse fields allows a clinician to place the results of a developmental assessment in a meaningful context for the individual child and leads to a better conceptualization of treatment options. For example, understanding the physiologic effects of prolonged malnutrition and episodic starvation in infancy (17,18) helps the clinician evaluate the relatively greater gross motor delays of a child with failure to thrive who has no other neurologic signs. Similarly, understanding the effects of a parent's affective disorder on a child's responsiveness to the external world (19) adds another dimension to understanding the infant's muted or absent social interactiveness, babbling, and smiling.

Finally, it is often during the synthesis process that the therapeutic effect for caregivers participating in the assessment is most evident. At the very least, caregivers often change their perceptions of their infant's capacities. They may see strengths in their infant they had not previously recognized or become deeply and painfully aware of weaknesses and vulnerabilities that they may or may not have feared before the assessment. Any of these changes in perceptions may affect the caregivers' view of themselves and of their role as caregivers. Also, infants often change during the assessment process, as their caregivers become more involved in the alliance with the clinician, and they experience, at least temporarily, another adult's concern and interest in their family. Emphasizing the potentially therapeutic value of an assessment underscores that the synthesis process is not simply wrapping up the assessment and conveying information, but is also a time to explore with the

caregivers the meaning of the process for them and their infant.

SELECTING AN INFANT ASSESSMENT TOOL

Below are some basic guidelines for choosing an infant developmental test that best meets the clinician's specific needs. These guidelines also help provide a framework for evaluating the usefulness of some of the various tests currently in use. Four areas of consideration are presented: purpose, sources of data, standardization, and psychometric properties.

Purpose

A developmental test may be useful for one or more of several different purposes: diagnosis, screening, and early intervention planning. Tests designed for these three purposes are quite different, and selecting the correct tests to match the stated purpose is essential. First, *diagnostic tests* are used to provide information necessary for either clinically or eligibility-oriented diagnoses. Second, *screening tests* are used when it is desirable to use a relatively brief instrument to identify infants who may be "at risk" for delayed development and would benefit from further diagnostic testing. Third, *intervention-planning tests* are used to plan an individualized early intervention program once children have been diagnosed and are used almost exclusively in early intervention and educational settings.

Sources of Data

Developmental tests for infants use one or more of at least three different types of data: direct assessment, incidental observation, and caregiver report. Direct assessment has the strength of potentially being standard in its presentation, so that an infant's performance may be directly compared to other infants with the assumption that the material was presented in a similar standard method. The limitation of direct assessment, however, is that it represents only a small sample of the infant's developmental repertoire and is influenced greatly by current issues regarding the infant's motivation, mood, comfort, and responsiveness to the examiner and the evaluative process. Caregiver report surveys are a useful addition to formal assessment, in particular to document behaviors that occur too infrequently to be observed in a clinical evaluation or to assess the caregivers' individual perspectives of their infant. However, caregiver reports should not be the sole measure of the infant's development, since they are highly subject to rater bias (20). Given the strengths and limitations of each of these sources of data, a comprehensive assessment should utilize multiple sources of data across multiple contexts.

Standardization

Test standardization involves the process of developing a consistent method of administration and collecting normative data regarding children's typical performance on the test. It is by this normative data that evaluators determine a specific infant's standing relative to the normative group. It is the responsibility of the test user, however, to decide whether a given test's standardization and normative samples are representative of the type of infants the test user plans to assess. Some tests are normed on very specific populations of children, such as children from a specific city or state or a particular economic status. The use of standard scores derived from these tests with infants from other localities or economic backgrounds, without specific empirical evidence to justify their generalization, is generally not recommended. Furthermore, in order to yield reliable results, tests (and their normative data) should be no more than about a decade old in order to keep pace with intergenerational escalation in test performance (21). Grossly outdated norms often yield inflated scores that may lead to erroneously disqualifying infants for needed services.

Psychometric Properties

The soundness of a psychometric test is judged based on its reliability (the ability to produce similar results under differing conditions) and validity (the collection of evidence that suggests that the test measures what it is supposed to measure). Several forms of reliability exist, such as test–retest (reliability over time), interrater (reliability between assessors), and internal consistency (reliability between items on the test). As a guideline, reliability coefficients of at least 0.90 for diagnostic tests and 0.80 for screening tests are recommended in each of these three areas of reliability (22). *Validity* is even more multifaceted. There is no single or preferred way to establish a test's validity. Rather, validity represents an accumulation of evidence that together builds a case that the test measures what it is supposed to measure. Specifically, infant developmental tests are expected to correlate significantly with other similar tests, to reflect developmental changes that result from expected maturation, and to be sensitive to the presence of diagnosable disorders with clear developmental manifestations.

REVIEW OF SELECTED DEVELOPMENTAL TESTS

A few of the more widely used developmental tests are presented in Table 4.2.2, and some of the most common examples are further described below, organized under three basic headings: neonatal, infant/toddler development, and screening.

Neonatal Assessment Tests

Brazelton Neonatal Behavioral Assessment Scale, Fourth Edition (NBAS-4)

The NBAS-4 (24) dominates the field of neonatal assessment and is intended to assess the neonate's current level of neurobehavioral organization, capacity to respond to the stress of labor and delivery, and adjustment to the ex utero environment. It is designed for use with neonates of 37 to 44 weeks' gestational age who do not currently need mechanical supports or supplemental oxygen. Though it is recommended that neonates be at least 3 days old before testing, it has been used on neonates during the first day of life. It takes about 20 to 30 minutes to administer, followed by about 15 minutes to record and score the neonate's performance. Although the NBAS was originally designed for use with full-term healthy newborns, it has been used extensively with premature and otherwise medically fragile newborns.

The NBAS is used to describe the range of behavioral responses to social and nonsocial stimuli, as the neonate moves from sleeping to alert states. Items assess the neonate's neurologic intactness, behavioral organization (state regulation and autonomic reactivity), and interactiveness and responsiveness with both animate and inanimate stimuli on the basis of 28 behavioral items and 18 reflexes. Lester et al. (40) have summarized the behavioral items as six factors (habituation, orientation, motor, range of states of alertness, regulation of state, and autonomic regulation) and use neurologic reflex behaviors to define a seventh factor. Each of the seven factors can be used to yield a numerical score describing the infant's performance in that area.

With training, interrater reliability for the behavioral items has been shown to be adequate, although a considerable degree of judgment is required of the examiner for assigning a rating to the neonate's responses, and temporal stability is poor for most items (41,42). The NBAS has been shown to be an effective intervention tool for increasing the maternal involvement and responsiveness of low-income and adolescent mothers (43) and has been shown to predict infant–parent attachment and subsequent infant development. Unfortunately, research not consistently shown the NBAS to be a good predictor of infant development much beyond the first year of life (44,45).

TABLE 4.2.2

Selected Formal Tests of Infant/Toddler Development

	Age	Domains[a]	Norm Sample	Reliability/Validity	Commen
Neonatal Assessment Tests					

Graham/Rosenblith Behavioral Test for Neonates (23)		M, TA, V, A, MT	Not applicable	Encouraging early findings	Seldom u
Brazelton Neonatal Behavioral Assessment Scale-4 (24)	37–44 weeks GA	NI, B, PS	Not applicable	High interrater reliability, weak test–retest, poor predictor beyond first year	Most wid used neonat
Infant/Toddler Development Tests					
Bayley Scales of Infant Development-III (25)	1–42 mo	Ad, Cg, EC, RC, FM, GM, PS	Large, representative	Excellent for cognitive and language, adequate for adaptive behavior and socioemotional	Most wid used a validate infant t used a standa
Mullen Scales of Early Learning (26)	0–68 mo	GM, FM, VR, RC, EC	Large, representative	Adequate to exceptional	Mostly us for todc and presch
Battelle Developmental Inventory-2 (27)	0–95 mo	PS, Ad; GM; FM; EC; RC; Cg (and subdomains)	Large, representative	Excellent reliability, adequate validity	Used conside
Griffiths Mental Development Scales—Revised: Birth to 2 years (7)	0–24 mo	Lm, PS, RC, EC, EH, P	Medium, all from UK	Mixed results	Mostly us Europe
Uzgiris–Hunt Infant Psychological Development Scales (28)	NA	See text	Not applicable	Adequate to exceptional reliability	Most pop Piageti infant t
Screening Tests					
Battelle Developmental Inventory Screening Test (27)	6–95 mo	PS, Ad; GM; FM; EC; RC; Cg	Large, representative	Strong correlation with full BDI	
Bayley Infant Neurodevelopmental Screen (29)	3–24 mo	N; RC; EC/M; Cg	Large; representative	Excellent reliability; promising validity	
Birth to Three Developmental Scale (30)	0–36 mo	EC/RC; Cg; PS; M	Small; questionable representation	Strong interrater reliability, but little evidence of validity	
Child Development Inventory (31)	15–72 mo	GM; FM; EC; RC; Ad; PS; L; N	Small; from St. Paul, MN	Little evidence of reliability and validity	300 parer report i
Denver Developmental Screening Test-II (32)	0–72 mo	GM; FM/Cg; PS; EC/RC	Large, all from Denver area	See text	See text
Developmental Activities Screening Inventory-II (33)	0–60 mo	15 sensory and problem-solving	>200 disabled children	Little evidence of reliability; valid for severely	Can be u with linguist

				delayed	and vis impaire childre
Developmental Indicators for the Assessment of Learning-4 (34)	30–71 mo	M; EC/RC; B; PS; AS	Large; representative	Acceptable reliability and validity	One of be screen for age
Diagnostic Inventory for Screening Children—fifth edition (35)	0–60 mo	FM; GM; RC; EC; AM; VM; Ad; PS	Small; all from southwest Ontario	Excellent reliability; limited validity	
Developmental Observation Checklist System (36)	0–72 mo	Cg; EC/RC; PS; FM/GM; Adj; PS&S	Adequate; representative	Sound reliability and concurrent validity	Parent re only
Developmental Profile-III (37)	0–155 mo	M; Ad; PS; AS; EC/RC	Large	Adequate reliability and validity	Parent re only
Early Screening Profile (38)	24–72 mo	Cg; EC/RC; M; Ad/PS; Ar	Adequate; representative	Good reliability; exceptional validity	One of be screen for age
Kent Infant Development Scales (39)	0–12 mo	Cg; M; EC/RC; Ad; PS	All from Northeast Ohio	Adequate reliability and validity	Primarily parent

[a]A, auditory responsiveness; Adj, adjustment; Ad, adaptive, self-help or daily living; AM, auditory attentioı memory; Ar, articulation; AS, academic or preacademic skills; B, behavior; Cg, cognitive or problem-sol EC, expressive communication/language; EH, eye–hand coordination; FM, fine motor; GM, gross motor letters; Lm, locomotor; M, motor or physical; MT, muscle tone; N, numbers; NI, neurologic intactness; P performance; PS, personal–social; PS&S, parental stress and support; RC, receptive communication/language; TA, tactile adaptive; V, visual responsiveness; VM, visual attention and memc VR, visual reception. A slash mark (/) indicates that multiple domains are assessed in the same scale c subtest.

Infant/Toddler Development Tests

Bayley Scales of Infant and Toddler Development-III (BSID-3)

The BSID-3 (25) is the most widely used measure of the development of infants and toddlers in both clinical and research settings. The BSID's extensive history of test development and validation makes it the most psychometrically sophisticated infant test on the market. The BSID is applicable to children from 1 to 42 months of age. Administration time is about 25 to 35 minutes for infants under 15 months and up to 60 to 90 minutes for children over 15 months.

The BSID is subdivided into five components following the five domains covered by federal early intervention law: Cognition, Language, Motor, Social-Emotional, and Adaptive Behaviors. The Cognition portion provides information on the child's problem-solving and cognitive abilities, the Language portion assesses the child's expressive and receptive communication, while the Motor component assesses the child's fine and gross motor skills. The new Social-Emotional scale (self-regulation and relationship formation) and Adaptive Behavior scales (adaptive and coping

skills) are mainly based on parental report.

Normative samples are large and nationally representative, reliability is acceptable to high. It is important to note that Bayley did not intend BSID scores to be interpreted as intelligence quotients. For the most part, performance on the BSID does not consistently predict later cognitive measures, particularly when socioeconomic status and level of functioning are controlled (46).

Mullen Scales of Early Learning

A relatively recent addition is the Mullen Scales of Early Learning (MSEL) (26). This revision of the original Mullen scales combined earlier versions of the test designed for infants and preschoolers into one test with continuous norms from birth to 68 months. The MSEL takes about 15 to 60 minutes to administer, depending on the age of the child (15 minutes at 1 year old, 30 minutes at 3 years, and 60 minutes at 5 years). The MSEL assesses child development in five separate domains: gross motor, visual reception (primarily visual discrimination and memory), fine motor, receptive language, and expressive language. The gross motor scale is only applicable to children birth through 33 months old and does not contribute to the overall early learning composite score. The normative sample is large, but somewhat overrepresentative of children from the Northeast. Reliability is acceptable to high. However, with normative data over two decades old, the MSEL is in dire need of renorming and may therefore overestimate scores.

Griffiths Mental Development Scales

Although the Griffiths Mental Development Scales (GMDS) is seldom used in America, it warrants a brief description due to its continued use in Europe and early influence on extending infant developmental testing internationally. The GMDS consists of two tests: *Griffiths Mental Development Scales—Revised: Birth to 2 years (GMDS 0-2)* (7), designed for infants birth to 24 months, and *Griffiths Mental Development Scales—Extended Revised: 2 to 8 years (GMDS-ER 2-8)* (47), for children 24 months to 8 years. The GMDS 0-2 scale consists of five domains: locomotor, personal and social, language, eye and hand coordination, and performance. The GMDS-ER 2-8 has the same five subdomains but also incorporates a practical reason subscale. The test is administered in about 1 hour, however, extensive training is required, and scales are only supplied to pediatricians or health care professionals. The GMDS 0-2 is normed on 665 UK children ages 0 to 2 from 1996. The GMDS-ER 2-8 is normed on 1,026 UK children ages 2 through 8 and is stratified according to 1997 UK Office of National Statistics data. The GMDS remains rather popular in Europe, Quebec, and South Africa, with some evidence of cross-cultural validity (48). However, the normative data are quite old and in need of updating.

Infant/Toddler Screening Tests

Denver Developmental Screening Test-II

The Denver Developmental Screening Test-II (DDST-2) (32) is one of the most popular developmental screening tests, especially in medical settings. This may be due at least in part to its brevity, as it can be administered in as little as 15 to 20 minutes. It is applicable for children from birth to 6 years. Items are scored based on a combination of caregiver report, direct assessment of the child, and observation. The DDST-2 produces one overall score, placing children in one of four descriptive categories: pass, questionable, abnormal, or untestable. Since the Denver-II was normed exclusively on children living in Colorado, caution should be used when employing this screener in other localities. The original edition of the DDST (49) had been criticized for not being sensitive enough, missing as many as 80% of children with delays or disabilities (50). Although the DDST-2 is a clear improvement over the original DDST, there is evidence that it now significantly over-identifies as many as 72% of children (51).

Early Screening Profiles

The Early Screening Profiles (ESP) (38) is applicable for children 2 through 6 years. It screens for cognitive, language, speech, physical, and social disabilities or delays that may interfere with a child's learning and warrant further diagnostic assessment. Children complete three different subtests: cognitive/language (assessing children's visual discrimination, logical reasoning, verbal concepts, basic school readiness skills), motor (assessing both fine and gross motor skills), and speech articulation. Total testing time per child is only 15 to 30 minutes, depending on the child's age. Additionally, the person who administers the test completes a 2- to 3-minute Behavior Survey documenting the child's behaviors during the assessment (e.g., activity level, attention span, cooperativeness, independence). Caregivers, or sometimes teachers, complete three different rating forms: the self-help/social profile (which provides a rating of the child's adaptive behaviors), the home survey (regarding the caregiver's perception of the child's home environment and caregiver–child interaction), and the health history survey (which provides information regarding immunizations, health problems, and prenatal health and delivery). Each of these rating forms can be completed in about 5 minutes. The ESP provides a wide variety of scores for all domains and subdomains, including age equivalents, standard scores, percentile ranks, and easy-to-use six-point screening categories. Screener cut-points can be set at several different levels in order to manipulate the false-positive to false-negative ratio. The primary drawback of the ESP is that it has no Spanish version. Psychometrically, the ESP is quite sound and represents one of the very best screening tests on the market.

CONCLUSIONS

Infant assessments are clinical explorations involving a fair amount of uncertainty and inference. While the medical diagnostic process always involves some element of uncertainty, the assessments made in infancy require of the clinician a particular comfort with uncertainty and the unknown. Though the latter half of the last century brought a veritable explosion of knowledge about infancy and the neonatal period, the more we learn, the greater we understand how inexplicably woven are the forces of development. As emphasized throughout this chapter, infant assessment involves far more than the infant and is as much a measure of the infant's environment as it is of his or her functional status. Thus, clinicians assessing infants are always dealing more with what they cannot know than with what they can, ever exploring the limits of predictive capabilities and constantly mindful of those limitations.

CHAPTER 4.3 ■ CLINICAL ASSESSMENT OF CHILDREN AND ADOLESCENTS: CONTENT AND STRUCTURE

JEFF Q. BOSTIC, MONA P. POTTER, AND ROBERT A. KING

The most common purposes of psychiatric assessment are (a) to determine if psychopathology is present, and if so, to establish target symptom priorities; (b) to determine what treatments/interventions might address the target symptoms and evaluate with the family and patient the relative benefits and risks of any proposed treatments; and (c) to gain understanding and build rapport that encourages patient and family engagement (1). The child (except as noted in identified sections, "child" will refer to "child and adolescent") is evaluated in the context of his or her functioning in the family, the school, extracurricular activities, and with peers, with sensitivity to cultural and community influences. The clinical assessment seeks to detect any developmental aberrations and maladaptive patterns, while casting a wide net to identify the patient's symptoms, as well as protective/resilience factors and relevant environmental variables and resources that may affect treatment outcomes. Many symptom constellations will respond to established treatments, so the clinician must prioritize intervention targets to devise a treatment plan that will address multiple problems, including comorbid disorders (2).

DISTINCTIVE ASPECTS OF THE PSYCHIATRIC ASSESSMENT OF CHILDREN

The psychiatric assessment of the child differs from the assessment of adults in several respects.

First, children rarely initiate psychiatric assessment or treatments themselves; rather, in most cases their parents or other adults provide the impetus for seeking treatment for the child. The child's behavior may cause greater distress to these adults than it does to the child. In some situations, the adult's expectations for the child may exceed the child's abilities, or the adult's own parenting or teaching style may be a poor fit with this child, yet these adults may seek means to alter the child to remedy this poor fit. On the other hand, children may not recognize their behaviors as problematic for others, or may not be receptive to changing these behaviors. Often these misbehaviors have "worked" by getting parents or teachers to avoid requesting the child to complete chores or tasks, or have culminated in others giving in to the child's requests. Children also may attribute problems to others and be unable or unwilling to accept their personal contribution to an identified problem. The psychiatric assessment of children thus requires consideration of both adult and child

contributions to the distressing behaviors for which evaluation is being sought. In addition, the assessment requires explicit attention to the child's perceptions of the problems and what the child desires to change (e.g., a child with severe anxiety might feel complacent with limiting activities and remaining in the comfort and safety of home versus pushing to tackle anxiety by engaging in anxiety-provoking situations).

Second, the child and the clinician are at different developmental levels, such that they may essentially speak different languages. The school-age child may lack the maturity to abstract "patterns" from isolated events, while the adolescent may perceive the clinician's questions as another inquisition resembling that of parents or school staff. Moreover, phase-specific developmental features may further impede communication. For example, young children may not trust unfamiliar adults, while adolescents may feel reluctant to express vulnerabilities they are experiencing (3).

Third, the child may function differently in different settings. The child may function relatively well in multiple domains (with family, at school or work, with peers), function poorly in only one domain, or may function poorly across multiple domains. This underlines the necessity of multiple informants (4), not only to discern accurately the child's overall functioning, but also to identify the child's areas of strength on which the clinician can build and to identify others (peers or adults) effective with the child and potentially able to introduce or reinforce more adaptive skills or behaviors.

Fourth, the child's presenting problems must be examined in a developmental context. The child may have a delay in skill development, such as delay in speaking or in areas of self-care, such as toileting. The child may not yet possess the social skills necessary to interact appropriately with age-similar peers, and thus will require interventions to introduce skills not yet present. The child's problems may also emanate from an inability to select appropriate coping/emotion regulation skills from an existing repertoire. For example, an anxious child may overgeneralize that "everyone" is negatively judging him and therefore feel unable to go to school and challenge those faulty cognitions, or an adolescent may understand that isolating worsens her depression, but still feel unable to get out of bed and reach out to friends. Finally, the child's problems may follow the loss of previously attained skills, often consequent to serious medical and psychiatric disorders, loss, or trauma. For example, a medically hospitalized school-age child may transiently regress with immature behaviors or loss of bowel or bladder control; adolescents developing schizophrenia may lose previously effective interaction and cognitive skills.

Further complicating this developmental context is developmental differences in presentation of mental illnesses. Many DSM diagnoses were primarily defined among adult samples. Although some disorders, such as obsessive–compulsive disorder, look quite similar in children and adults, other disorders, such as major depression or PTSD, can present notably differently in younger patients as compared to adults (Chapter 5.4.2). For example, in major depression, some school-age

children may be less likely than adults to manifest dysthymic, self-accusatory feelings and more likely to manifest irritability or somatic symptoms (e.g., headaches, stomachaches, body pain). Discerning "categories" of mental disorders in children can be difficult, since symptoms overlap across diagnostic categories; more importantly, numbers of symptoms in children predict psychosocial function more so than the diagnostic category where a child appears to best fit (5). A dimensional approach can, therefore, provide additional formulation insights; efforts to consider common underlying tendencies (e.g., difficulty tolerating emotions) and determining where a particular child fits on the depressed mood axis, the inattention spectrum, and the impulsive axis, for example, may ultimately prove fruitful for prioritizing intervention targets.

Finally, an underestimated but critical facet of the psychiatric assessment of children is the necessity for forming alliances with the multiple parties, including among the clinician and the child, the parent, the school, and any additional outside agencies. A breach or rupture in any of these relationships can markedly impair treatment efforts. It is during the assessment phase that efforts must begin to identify and align the agendas of these various treatment "partners" to enhance any intervention efforts. Parental permission should be obtained to contact and elicit information and collaboration from the various relevant parties who may have important information or who play an important role in the child's progress; such contacts include step- and noncustodial parents, teachers (by phone, via school records, and/or requested rating scales), and primary medical care providers. Following the initial evaluation, follow-up contacts with parents living apart from the child, school staff, and other health providers can often help clarify obstacles to treatment and can help invest others in the child's improvement.

CONTENT OF THE CLINICAL INTERVIEW

Core contents of the clinical assessment of children and adolescents are common across purposes; these components are summarized in Table 4.3.1. The core components are similar to the adult psychiatric assessment, though with added emphasis on developmental and environmental (e.g., family, school, peer, media) factors and contributions. They illuminate the need for a consistent, thorough assessment of the multiple variables that may contribute to the child's presentation, and the importance of synthesizing the input from multiple informants to derive an accurate picture of each child's unique predicament.

Depending on the complexity of the problem(s), the initial assessment might need to be completed over more than one session; priorities of the initial evaluation include safety assessment, rapport and empathy building (so that they are willing to come back), clear understanding of what the acute problem is and how it is affecting the child and system (family, school, peers), barriers to seeking/engaging in treatment

as well as strengths and motivating factors, and list of invested others with whom to collaborate and seek additional information.

TABLE 4.3.1

CONTENT COMPONENTS OF THE PSYCHIATRIC ASSESSMENT OF CHILDREN AND ADOLESCENTS

Content Component	Primary Informant	Additional Resources
Reason for referral	Usually parents/guardian, sometimes school or legal agency	Letter from school or other agency seeking evaluation
History of present illness/problems(s)	Child and parents	Referral source, pediatrician/primary care provider
Past problems	Child and parents	Structured interviews, rating scales
Safety assessment	Child and parents	School
Comorbid symptoms	Child and parents	Structured interviews, rating scales
Substance use	Child and parents	Toxicology screening (as relevant)
Previous assessment/treatment(s)	Child, parents, clinicians	Mental health records
Developmental history (motor, cognitive, interpersonal, emotional, moral), trauma	Parents, school staff	School records, including Special Education Evaluations, home videos (as relevant)
Family history	Parents	Genogram
Medical history	Parents, health care provider(s)	Review of symptoms checklist, laboratory tests (as relevant)
Child's strengths	Parents, child, teachers, coaches, peers	Activity video (sports, music); cognitive, school, neuropsychological testing
Environmental supports	Parents, child, adults familiar to child	Activity schedules (scouting, teams), afterschool/summer programs, mentorships/Big Brother or Sister relationships
Child's media diet	Parents, child, caregivers, siblings	Media diary, Apps on phone
Mental status examination	Child, Clinician (observations during interview)	

Reason for Referral (Chief Complaint)

Clarity about who actually initiated the referral, their motivations, and what changes they seek is essential to the success of any evaluation. While parents may schedule an evaluation, opening questions about who suggested it, who recognized a need for an evaluation, or who is most uncomfortable with the child's behavior may all help clarify the impetus for the evaluation. More importantly, clarifying the circumstances and concerned individuals driving the evaluation request may reveal the expectations of relevant parties and their willingness to implement treatment recommendations.

For example, a parent may indicate the school or a grandparent identified distressing behaviors in the child. The parent may be required to obtain an evaluation for the child to return to school. The expectations of these various parties may in fact be in conflict and must be reconciled if effective treatments are to be implemented and for adherence to occur. For example, the school may seek to have parents manage the child differently or consider medication treatments, while the parents may wish for the evaluation to validate their current parenting efforts or provide diagnoses and recommendations that would yield additional school services. Similarly, grandparents may wish for different parenting approaches, while the parents may seek confirmation that their current approach is appropriate.

History of Present Illness

Current Problem(s)

Narrative. The evolution of the child's problem should be elicited by the clinician mindful of the pain most parents encounter while recounting the deterioration or anguish of their child. To minimize this distress, and to obtain a full description, clinicians should provide parents some opportunity to chronicle this history in their own words. Parents diverge widely in terms of their own experience with and views of psychiatry, how they understand people's behaviors, and in their acceptance of alternatives to their current responses. Attention throughout the interview to these parent variables allows the clinician to explain behaviors and select interventions in terms acceptable to these particular parents. The more treatment recommendations can be framed within the parents' own description and understanding, by using the parents' words or concepts, the greater the probability parents will feel heard and collaborate in treatment.

As the parents describe the history of the problem, the clinician attends to the context in which the behavior emerged and occurs, changes in frequency and intensity of the behaviors, and the current progression of the problem. The clinician ultimately needs also to inquire directly about specific instances of the child's problematic behaviors, parental responses to these behaviors, and the child's response to current parental interventions.

Functional Assessment of Problem Behaviors. Since any given symptom or behavior (anxiety, inattention, arguing, theft, hallucinations) may have quite different meanings, functions, and clinical implications in different children, it is important not to jump immediately from symptom to diagnosis. The clinician may need to inquire directly about the *functions* of the problem behavior, including any secondary gains for the behavior (tantrums diminish parental expectations of chore completion, complaining of headaches every morning decreases time spent in a painful school class, running away causes parents to unite in efforts to find the child). Identifying

specific antecedents and precipitants of the problem behavior and its consequences, both for the child and for others (including the family or classroom), may provide valuable insights into the functions of the problem behavior. In addition, the clinician should clarify the impact of the problem on the patient's quality of life, with particular attention as to whether the problem is specific to one functional domain or whether the behavior pervades multiple or all areas of the child's functioning, such as home, school, extracurricular activities, and with peers.

Problem behaviors may reflect an underlying disorder within the child, but may also reveal a problem within the child's environment (6). For example, a particular teacher, peer, or adult may contribute to the child's distress, although it is the child's symptom that is being labeled as the problem behavior. The *fit* between the child and a particular teacher, peer, or adult may culminate in expression or exacerbation of the child's symptoms. Accordingly, even when the child's symptoms occur pervasively across multiple domains of life (home, school/work, peers), attention to changes in school circumstances and peer and adult/parent networks may clarify forces fueling the symptoms.

Daily Routine. Given the impact a breech in basic functioning can have on exacerbating and perpetuating symptoms, it is helpful to inquire about a child's current functioning in everyday essentials such as sleeping, eating, physical activity, and self-care (developmentally appropriate tasks, e.g., brushing teeth, showering). Asking parents and child to map out a typical weekday and weekend day (morning to next morning) for the child can paint a picture and provide insight into how much time is being spent on various activities and with what level of ease/distress (e.g., getting ready for school, doing homework, extracurricular activities, social media/video games, sleep), as well as offer opportunities for interventions (e.g., sleep hygiene/bedtime routine for a child with poor sleep, behavioral activation for a sedentary and isolated child).

Past Problems

Significant past problems that have impaired the child should be identified, as this provides a historical context for understanding the current problem. It is especially important to understand whether a problem has been persistent since early childhood, is intermittent, or represents a deterioration from a previously better level of functioning. (If the latter, the inquiry naturally leads to the questions of what events and circumstances have accompanied this deterioration.) Identification of significant past problems that have interfered substantially with functioning at home, school, or with peers can also be facilitated through the use of screening instruments (see Chapter 4.6).

Inquiring about past episodes of harmful comments or acts may reveal important developmental progressions or patterns that warrant intervention. Headbanging or

self-injurious behaviors may reveal underlying sensory disturbances, sometimes seen in developmental disorders; thoughts or comments about death may reveal suicidality; and self-harmful acts such as burning or cutting may reveal primitive coping mechanisms (7).

Safety Assessment. A safety assessment, both through direct and indirect questioning, may reveal need for close monitoring to preserve safety while diagnostic or treatment interventions occur. For example, directly asking a child if thoughts of death or not wanting to be alive have occurred will give a clinician a sense of how stuck and hopeless the child feels. Indirectly paying attention to how much or little the child talks about future-oriented events and meaningful connections, such as looking forward to an upcoming concert with friends, can help the clinician gauge how engaged and connected the child feels, thus providing insight into protective factors. Typical parts of the core safety evaluation include:

- Current suicidal ideation, intent, plan, means (e.g. access to pills if plan is to overdose)
- Past suicidal ideation, intent, plan
- Past suicide attempt(s), including method of the attempt, result of the attempt (e.g., hospitalized?), perception about outcome (i.e., how the child feels about the attempt being unsuccessful)
- Past and current nonsuicidal self-injury (NSSI) (e.g., cutting, burning), purpose of this behavior, does it fulfill that purpose (feelings before/during/after), desire to continue/stop, need for stitches/medical attention
- Current conflict(s); thoughts, plan, intent to harm anyone
- Past aggression/violence toward others

Additional acute safety issues important to investigate include substance abuse, impulsivity, risky behaviors, restrictive eating, agitation/aggression, and access to guns/weapons. This information should be put in context of information gained through the entire psychiatric interview to help determine level of risk.

Comorbid Problems

As parents describe the symptoms that appear most prominently in their child, the clinician begins thinking implicitly about what diagnostic categories (or other means of conceptualizing the symptoms) might apply. Symptom constellations may be described by a parent in such a way as to suggest one particular diagnostic category, particularly when parents have heard from other parents, books, or Internet resources about potential diagnoses. However, it is important to recall that psychiatric symptoms often overlap between various disorders, so consideration of disorders that may share similar symptoms should be considered. For example, inattention may occur in children with attention deficit hyperactivity disorder (ADHD), but also among children with bipolar disorder, posttraumatic stress disorder, anxiety

disorders, or autism spectrum disorders, as well as in children who may be preoccupied with obsessions that distract them from focusing on what others are discussing.

Comorbidity is common in childhood psychiatric disorders and can complicate the course of treatment. For example, a child presenting with depression might also struggle with severe anxiety; the child will therefore require interventions not only to address mood symptoms, but also to tackle fear and avoidance (that also worsens the depression). Conducting a Psychiatric Review of Systems by asking screening questions about core DSM-5 diagnostic categories will help inform the clinician about possible comorbidities requiring further investigation. In addition, Section III of DSM-5 provides a Cross-Cutting Symptom Measure for Children ages 6 to 17, which assesses 12 domains of functioning across psychiatric diagnostic categories (i.e., somatic symptoms, sleep problems, inattention, depression, anger, irritability, mania, anxiety, psychosis, repetitive thoughts and behaviors, substance use, and suicidal ideation/suicide attempts). Screening instruments can also be useful to provide comprehensive information about less conspicuous conditions. This may be particularly important in detecting *internalizing* disorders, such as anxiety or mood disorders, which may be difficult for children to articulate, or which may be less troublesome or apparent to adults than disruptive *externalizing* disorders.

Substance Use History

Some symptom patterns, such as substance use, are particularly worrisome, both in terms of the direct hazards they pose to the child's development and as markers for a broader constellation of risk behaviors (8). Hence, it is particularly important to inquire regarding the child's exposure to and use of substances, including tobacco, alcohol, synthetic, and illicit substances, and how they may contribute to current symptoms. Asking about substance use in the child's peer group, views of use (e.g., "is it ok to occasionally drink socially?"), and perceived risk of use (e.g., "how harmful is it to smoke marijuana?") might provide insight into factors increasing likelihood of use. Previous exposures (including prenatal), contexts surrounding use, and effects of substances may impact treatment. Some children identify specific reasons for taking certain substances, while others proceed through many substances with diverse motives for taking or continuing use of these agents. For example, some children perceive that substances temporarily alleviate some of their symptoms (anxiety, depression) and so "self-medicate." In such cases, clarifying what impact these substances have on symptoms can clarify symptom priorities of the child, as well as possible intervention points more likely to be embraced by the child.

Previous Testing and Treatment(s)

Previous evaluations, including educational and neuropsychological testing, as well as past treatments, including medications, therapy, hospitalizations, and alternative treatments, may provide useful information about the evolution of a child's problems. Chronologic assessment of past treatment efforts may reveal seasonal patterns or escalation of a disorder. In addition, past treatment history may suggest which treatment modalities have been tolerable and effective (or not) for this patient (and family), signaling adherence issues or approaches that will be important in this case.

Developmental History

The developmental history is a detailed account of the child's development from birth forward. This history includes bodily/basic function regulation, motor development, language development, cognitive growth, social development, emotional regulation, moral development, and exposure to trauma. Parents vary widely in their recollection of precise timing of developmental milestones. Comparisons with other siblings or children, comparative recollections by different adults, and review of earlier videotapes of the child by the parents may improve the reliability and completeness of parent reports.

Bodily/basic functions include sleeping, eating, and toileting (including inquiries into bedwetting and soiling). Challenges in achieving milestones in these areas may result from or exacerbate episodes of difficulty. Similarly, previously attained skills may suddenly be lost, sometimes signaling the importance of emotional events at particular times. Eating behavior has become complicated as the availability of various types of food and times to eat have increased. While hunger remains a risk factor for psychopathology (9), obesity has become more common among younger people and markedly increases risk for both physical and mental illness (10,11).

Motor development includes milestones such as standing, walking, throwing, running, hopping, skipping, and playing sports or musical instruments. Fine motor and gross motor skills may not be congruent and therefore require specific inquiry into possible areas needing intervention or accommodation. Inquiry as to how the child enjoys or fares at activities such as sports and/or music may suggest treatment options through nonverbal modalities. In addition, history from parents may clarify periods when the child could not employ skills or became frustrated in attempting activities requiring motor coordination.

Cognitive development usually begins with the child's verbal and attentional skills. Assessment of the child's academic progression in preschool and school can reveal cognitive weaknesses that may contribute to the current problem, or potential strengths to be harnessed to ameliorate the current problem. Specific inquiry concerning learning disorders—e.g., reading, writing, and math skill progression—may reveal global difficulties or uneven skills in development (12). Evaluation of executive functioning skills, particularly at times of transition to middle and high

school, can uncover underlying skills deficits that manifest through emotional and behavioral challenges. It is important to bear in mind that adequate progress in school requires more than adequate innate cognitive abilities; it also reflects factors such as the child's motivation, freedom from distraction, attitudes toward authority, capacity for peer relations, tolerance for frustration and delayed gratification, and degree of parental support for learning.

Interpersonal development assesses how the child interacts with others, particularly family members, other children, and adults. Early interactions, especially with parents, provide important information about this child's comfort around others and the environment. For example, early aloofness, disinterest in others, absence of interactive play with parents or attention to objects pointed out by parents may be early markers of autism spectrum disorder. The child's (and parents') reactions to significant changes in the social environment of the home can be important precipitants for the child's symptoms, particularly births/deaths of family members, marital changes (separations or conflicts, divorce, remarriages), and changes in caretaking arrangements (parent returning to work, or custody/visitation changes).

The child's interactions with peers and adults outside the family are also important. Interactions with other children and preferences in play activities and friends (gender, age, interests) are important data for assessing the child's social skills and interest in relating to others. Stability of relationships, numbers of friends, types of activities shared, and expectations of peers ("plays with me when I want," "plays what I want to play," "helps me out if I need it," etc.) can reveal strengths, sources of difficulty, or persistent maladaptive clashes where only the names of the antagonists change.

Emotional development and *temperament* is a key component in the evaluation of every child. A child's capacity to recognize his or her own mood state and to self-soothe or regulate negative affect should be investigated. Prevailing moods can be described by parents, as well as past suicidality, irritability, specific fears and anxieties, and conditions associated with the child's happiness and pleasure. Whether the child can recognize when a mood is mild or severe, and what steps the child will take when anxious, sad, or when encountering change, boredom, or disappointment provide insight into vital coping mechanisms. Circumstances which provoke aggression or anger and the child's responses and capacity to accept input or direction from others may clarify intervention options such as parenting or behavioral treatments. These traits commonly exist along a spectrum, so that bullying, for example, may have started as assertiveness and progressed to exploitation or intimidation of others.

Assessment of the child's *moral development* provides an important gauge of whether the child's conscience or moral values are too lax, too harsh, overly focused on particular areas, or uneven and out of proportion to daily events. The child's religious, cultural, and ethical views and practices and how those fit with those of the

family also provide helpful information guiding potential treatment interventions. Similarly, the child's ability to recognize the plight of others, to recognize impacts of decisions on others, to reconcile principles with mistakes the child makes, and to acknowledge and correct mistakes often provides clarity about the child's strengths and limitations.

Trauma experienced at any stage of the child's development can substantially impact or even arrest development. Investigation of not only actual events (such as documented physical or sexual abuse), but also of events perceived traumatic by the child and the vicissitudes of these events for the child and family shed important light on the child's behaviors and patterns of relating to others. Identifying episodes of trauma, the events surrounding the trauma, the child's role in disclosing such trauma to others, and the reactions of adults to such disclosures are important for the clinician to recognize and address. It is also essential to ensure current safety of the child, such that any risk of re-traumatization is minimized.

Family History

Parental variables may impact the child's problems and warrant examination. First, family conflict, or differences in parenting style, may culminate in the child manifesting symptoms; however, the converse is equally true, in that disturbed behavior by a child may stress otherwise adequate parental coping skills or provoke conflict between parents (13). Parents may have grown up themselves with different parenting practices in their families of origin that they wish to employ, or avoid, and these influences are important to understand in assessing the consistencies and discrepancies within and between each parent's style. In the face of a child's distressing behaviors, parents may attempt a wide variety of approaches, some uncharacteristic of their usual parenting style, poorly conceived, and enacted at inopportune times (e.g., unenforceable threats during a tantrum); such responses may not improve the problem but do increase parental guilt and hopelessness. Accordingly, the clinician must be mindful that the approach parents ordinarily employ may not be described if it does not work with this child. Clarifying the evolution of the approaches parents have attempted for this child's problems, and how these approaches may have differed from approaches employed with their other children, may help the clinician disentangle child and parent contributions to the current problem. In addition, exploring the child's compliance with family rules and expectations, the consequences for noncompliance, and the child's reaction to parental interventions in response to noncompliance often provide opportunities for behavioral interventions to diminish symptom expression. It is important to identify parents' style of limit setting in a variety of areas. For school-age children, these concern hygiene; sleep; diet; television, Internet, and video game use; and the expression of aggression. For adolescents, it is additionally important to know what

sort of expectations parents do or do not set regarding curfew, dress, leisure activities, and choice of friends. Effective parental monitoring of an adolescent's activities, whereabouts, and peers is an important aspect of problem behaviors and usually reflects not only parents' efforts at active, close surveillance, but also a close parent–child relationship that encourages open communication and child disclosure (14).

Second, parents may have problems with the child at particular developmental periods. Certain developmental stages may have particularly challenged the parent's skills or coping responses, or may have reminded the parent of a painful time in his or her own childhood. Discussion with parents about how they navigated past difficulties with this child, their rationales for certain parenting practices, and their expectations (and fears) during this given developmental phase of the child often provide clues about potential parental contributions to the problem. Similarly, information about parents' cultural, educational, occupational, and religious background may reveal not only sources of adversity or conflict between parents or family members, but also sources of pride and resilience that inform interventions to enhance treatment adherence among parents and children.

Third, parental genetic contributions remain an important variable to consider, particularly since some parents perceive that the child's psychopathology may be attributed to one or the other parent based on that parent's personal or family history. Few if any common psychiatric disorders appear exclusively through genetic transmission alone, although increased vulnerabilities to various disorders are likely. In addition, growing up with a parent who has struggled with a psychiatric disorder such as depression, anxiety, psychosis, or substance abuse is likely to have an impact on the child, over and above any genetically transmitted vulnerability. Tactful but thorough investigation into psychopathology in each parent and among the extended family may suggest which disorders or general conditions (mood, anxiety) may be more probable. Patterns can also be visualized by constructing a genogram, particularly in complex families with multiple psychopathologies. Although unspoken during psychiatric evaluations, many parents fear that their other children may be destined to suffer psychopathology when one sibling manifests a disorder, so clarification of genetic contributions to expression of disorders can often be helpful in reducing unwarranted fear, guilt, and distress among parents.

Divorce, separation, and single-parent family circumstances may stress all family members, including the children. Even when parents part amicably, children may have difficulty with change from what has been familiar. Similarly, even in circumstances where parents and children experience reduced conflict after parents separate, children sometimes exhibit symptoms which coincide with marital changes. The child's symptoms may reveal overwhelming stress or fear, but also may reveal efforts to reunite family members. In addition, children may exhibit symptoms months or years after separations as difficulty adjusting to new roles or environments occurs

or as they enter a new developmental phase (15). Therefore, the clinician should be attuned to how the divorce/separation is affecting each member of the family, e.g., what is the child's understanding of circumstances leading to divorce? How does communication between parents occur (e.g., routinely and amicably vs. angrily and only via child as messenger)? Are parents reasonably consistent in their approach to parenting (vs. one parent being "the mean/difficult parent" while the other becomes the "fun/easy parent")?

Adoption is usually a positive event for the child and for the adoptive parents. The circumstances of the adoption warrant tactful attention by the clinician, including age of the child and biologic parents, the degree of ongoing contact with or interest in biologic parents, the child's understanding of the adoption and attitudes about the biologic and the adoptive parents, and how the adoption is discussed at home. In addition, adoptive parent expectations and feelings about the adoption, particularly as their child now undergoes a psychiatric evaluation, may reveal underlying parental fears, guilt, or disappointments. However, the family system is currently configured, the clinician should inquire about how the family system functions, with whom the child spends time, and the nature of the relationships between the various household members and the child. Boundaries and alliances, conflicts, and the child's affinities or resentments of other family members should be determined. Family communication and problem solving, including how issues of disagreement are handled, should be assessed. The emotional tone of families vary widely from constricted to overly expressive and dramatic, and should be examined both by observation of family interactions during the interview, as well as by direct inquiry. Clarification of family stressors that are chronic family stressors (family member illness or disability) or acute (sudden illness, job loss/change, financial or legal difficulties) may identify determinants of the child's current problems as well as potential targets for intervention.

Medical History

Obtaining consent to contact the patient's pediatrician allows for collaboration across health care providers. Checking into compliance with well-child visits and pediatrician recommendations (e.g., vaccinations), and pediatrician's involvement in ongoing care can provide helpful information related to resources and follow-through.

Medical conditions experienced by the child should be identified beginning with conception (including any difficulties the mother had in conceiving or the use of assisted reproductive technologies). Pregnancy complications, birth difficulties, extended hospital stays, and medical illnesses requiring recurrent or ongoing treatments (e.g., asthma, diabetes) should be investigated, since these appear to increase the child's risk for psychopathology (16). In addition, inquiry into

hospitalizations, emergency room visits, or surgeries can help shed light on severity of illness as well as the child's fears or parental over/underprotectiveness.

Age of menarche and stage of pubertal development should be inquired about when relevant. If the child's weight and/or stature is out of the normal range for age (as plotted on a standard growth chart), a detailed review of the child's growth history and eating habits should be made in consultation with the child's pediatrician.

Accidents or illnesses with a potential for central nervous system impact, such as lead exposure, seizures, head trauma, and loss of consciousness, deserve specific inquiry.

Medications and Allergies

A list of all medications (including over-the-counter and naturopathic agents), indication for the medication, length of treatment (or dates taken if known), max doses, benefits, side effects, compliance, and reason for discontinuation should be obtained for all current and past medications. Additional attention to patient and family attitudes to use and effects of medication can provide opportunity to address potential sensitivities and barriers to treatment.

Allergies, particularly to medications, also should be elicited and documented.

School and Educational History

As noted earlier, putting the child in context of family, school, and the broader environment is essential in gaining a full understanding of the presenting problem and possible interventions. Creating a timeline by grade level provides opportunity evaluate connections between academic progress (e.g., report card grades, standardized testing, evaluation of learning disabilities), behavioral challenges (e.g., disruptive classroom behaviors, tardies/early dismissals, absences/school refusal), social stressors (e.g., bullying, social exclusion, or isolation), environmental events (e.g., death of beloved family member), and interventions (retentions, accommodations/modifications [504 plan/IEPs], treatment) to evaluate areas in need of particular attention. Focusing on notable years/grades that went particularly well or poorly can shed light on the impact of classroom/teacher fit, social experiences—including bullying (17,18), and learning challenges/disabilities on progression of symptoms. Understanding the culture of the school and classroom, the system's approach to bullying and social/emotional support, and the most trusted allies/adults at school can provide additional insights and opportunities for interventions.

In addition, gaining an understanding of how the child views himself as a student (e.g., "I'm really smart, but my emotions get in the way" versus "The work is just too hard for me." versus "My teacher doesn't know how to teach so that I can understand") and what the child's priorities are as a student (e.g., valuing education

and progressing through high school to college vs. wanting to drop out as soon as possible) can provide insight into self-esteem and self-efficacy and possible need for additional school-related interventions.

Child Strengths and Supports

In addition to clarifying the child's problems, the evaluation simultaneously elicits the child's areas of strength so that interventions can build on these existing assets rather than focusing exclusively on areas of weakness. It often can be helpful to start an assessment by asking parents what the like about their child, or what their child does particularly well. In addition, finding out what the child takes pride in or values offers an opportunity to help boost the child's sense of efficacy; this can be a nice balance given that children presenting for evaluation often experience an emphasis on negative behaviors and events.

Interests, hobbies, and talents of the child should be obtained from both the child and the parents, since these accounts may not match or may even be in conflict. Parents may have aspirations for their children that the child does not share, or the child may have fantasies beyond apparent abilities. In most cases, though, the child will have some identifiable interests or abilities that serve as potential points of connection with peers and adults (including the therapist) and may serve to facilitate therapy. Exploration of the child's interests, including newly emerging ones, may allow the interviewer to anchor recommendations or treatment metaphors to language or subjects familiar to or valued by the patient. Similarly, the child's and parents' accounts of time spent in an activity (10 years of ballet and modern dance) or perceived fruits of the child's labor ("I won trophies twice," vs. "I've lost most games I've played in") illuminate what effect the activity has had on the child, including pride or disappointment, as well as the parents' and the child's own expectations.

Although many children must contend with moves or changes in the family constellation, other *environmental supports and buffers* often provide stability and even sanctuary and warrant investigation. Adults other than the parents (such as grandparents and other relatives, coaches, teachers) may play significant, ongoing roles in the lives of children, while community involvements, such as church groups, athletic team participation, outdoor clubs, musical ensembles, or even preferred places to convene, may provide opportunities for intervention or support in natural settings on a regular basis.

The Child's Media Diet

In an information-processing society, children are exposed to immense doses of media, including television, music, videos, electronic games, cell phones, e-mail,

and social media platforms and apps. These media, which may provide exposure of the child to violent and sexually provocative material, can have positive or negative effects. It is important to clarify which media the child uses, how much time each day is spent with these various media, how the child decides what personal information to post and share publically, and what consequences these media have on the child (e.g., in response to watching action television shows the child becomes more violent vs. has developed interest in Asian food through watching cooking programs, or listening to music at school serves to distract the child from classroom instruction vs. helps the child calm down on the bus or ignore other disruptions) (19). Social media can be used to multiple ends, which may be adaptive (maintaining friendships with camp friends), problematic (bullying, harassment, or dangerous exhibitionism), or both (permitting a socially anxious child to maintain a modicum of electronic social contacts, but at the cost of face-to-face relationships) (20). As with other aspects of parental monitoring, the degree of parental awareness and appropriate limit setting regarding television, video games, and social media is important to determine, in part as an indicator of parental structure and expectations. As with other of the child's interests, preferred television show, favorite movies, favored musicians, or bands provide a common language to examine topics, as well as clues about the child's aspirations and behavioral self-expectations ("[Music idol] swears at adults all the time, so why can't I?") (21). Asking a child to describe an episode of a favorite TV show or movie also provides a convenient picture of the quality of the child's social language and grasp of others' motives and feelings.

Mental Status Examination

The mental status examination is an essential part of any psychiatric interview, as it provides direct information about how the child presents and interacts with the clinician. The mental status examination includes a clinical description of the child's appearance, engagement, behaviors, mood and affect, sensorium, apparent cognitive functioning, and thought content and process. Although often conceptualized as a separate component that is distinct from the history-taking interview, in reality much of the mental status examination takes place implicitly as the clinician interacts with and observes the child during the child and family interviews. Although some components of the examination will require specific inquiry or examination (such as orientation, memory, fund of knowledge, and mental contents), most will be noted as the clinician organizes his or her ongoing observations of the child according to the elements of the mental status examination. A format for the child mental status examination is provided in Table 4.3.2.

In addition, the mental status examination provides an opportunity for further screening of organic or neurologic contributions to the child's symptoms. A mini-mental status examination (MMSE) (Table 4.3.3) can provide more detailed

assessment of an older child's higher-order mental functions, including orientation, attention, memory, language, and constructional ability (22). This MMSE contains items appropriate for older children, although some modified versions provide questions for younger patients (23). More reliable and detailed assessment of a child's speech, language, intellectual, academic achievement, attention and executive functioning, memory, and complex thinking requires standardized psychometric testing (Chapters 4.4 and 4.5).

STRUCTURE OF THE CLINICAL INTERVIEW

While the steps in the process of the psychiatric assessment of the child may unfold in multiple ways, a stepwise approach, individualized by the clinician for the requirements of each specific case, helps ensure thoroughness. More importantly, the quality of the information obtained from which all diagnoses and treatment planning will follow is contingent on the approach the clinician employs, and how well this approach fits the particular patient. A sample checklist for the preparatory stage of the psychiatric assessment of children is summarized in Figure 4.3.1. The clinician or staff may begin completing such a checklist during the initial phone contact with the child's family, although the entire checklist may not be completed until after the assessment.

Preparatory Phase of the Child Interview

Preparation is paramount in child psychiatry interviews. Families are often unfamiliar with what occurs during such an assessment, and concern by the child or the parent that they will be "judged" is almost universal. Unlike routine well-child visits with a pediatrician, a child psychiatry interview is rarely perceived by parents as a mental health checkup for their child, but rather as potentially indicative of their failures as parents. Invocation of a psychiatric diagnosis may help exonerate some parents from feelings of guilty (but sometimes spurious) responsibility for the child's presenting difficulties and, indeed, some parents may seek evidence of a "chemical imbalance" outside their control as responsible for the child's symptoms. Others, however, might view a psychiatric diagnosis as stigmatizing for their child (and themselves). Accordingly, interactions prior to the actual interview can help clarify parental fears and expectations. For example, parents may report, "I did toilet training wrong, and now my child—…" as they search for the root of the child's current problems. Similarly, parent anxieties often emerge, as some parents report, "My child only acts badly toward me—I bring out the worst in my child," fearing they uniquely cause the child's symptoms. The parent interview also provides clues as to what difficulties may be encountered in trying to change parental behavior, such as how overwhelmed a parent may become when even basic interventions are

suggested for them to enact (e.g., in response to questions such as "What would happen if you were to simply turn the television off and tell him it is bedtime?"). At the other extreme, some parents may have hopes or expectations that the clinician cannot fulfill, for example, "You [the child psychiatrist] need to tell him how good he has it at home" or "Tell him if he is gay I will disown him and throw him out of the house." Such expectations may require clarifying what expectations the child psychiatrist can or cannot fulfill. Parents may come with other preconceived agendas, such as that their child is bipolar or that they are determined that under no condition will their child ever receive any medication. Preparing parents for what to expect during the assessment diminishes parent and child anxieties, and initiates a process for shared goals and appropriate parent and child expectations. Sample letters clarifying the assessment are provided in Appendices 4.3.1 and 4.3.2.

TABLE 4.3.2

THE MENTAL STATUS EXAMINATION IN CHILDREN

Appearance	Appears stated age, notable physical attributes, clothing, hygiene and grooming
Orientation and alertness	Self (name), place (location), time (awareness of morning, day of week, month, etc., varies by age), situation (why here)
Manner of relating to clinician and parents	Ease of separating from parents, quick or slow to warm up, level of engagement, eye contact, eagerness to please, defiance
Activity level	Psychomotor agitation or slowing, fidgeting, goal-oriented or erratic movements, coordination, unusual postures or motor patterns (e.g., tics, stereotypies, akathisia, dystonia, tremors), compulsions
Speech	Spontaneous or forced, fluency (including stuttering, speech impediments), rate, volume, prosody, latency
Mood	As described by child, e.g., "happy," "sad," "mad"
Affect	Congruent with mood? Examples: anxious, blunted/restricted, dysthymic, euphoric, euthymic, flat, full range, irritable, inappropriate/odd, labile
Thought process	Logic, linear, goal-directed, perseverative, circumstantial, disorganized, tangential (consider age-appropriateness), looseness of associations, word salad (incoherent, clanging, neologisms) Poverty of thought (latency, blocking) Racing thoughts, flight of ideas Abstract vs. concrete: Proverbs (e.g., what does "Grass is always greener in somebody else's yard" mean?)
Thought content and perceptions	[note: ego-syntonic or dystonic] Thoughts to harm self or others (plan, intent) Obsessions, delusions, ideas of reference, paranoia Depersonalization, derealization, hallucinations
Attention, calculation, working memory	Need for redirection/repeating, length of time sustained in activity, degree to which child shifts from activity to activity, distractibility (e.g., to outside noises) Serial Sevens (start from 100, subtract 7) or Digit Span (repeat 2–5 digit strings forward and backwards), spell "WORLD" backwards
Memory	Immediate (repeat words) Short-term (recall three words at 2 and 2 min) Long-term (recall events from past week, month, etc.)

Intelligence/fund of knowledge	Age-appropriate recognition of letters, vocabulary, reading, counting, computational skills Age-appropriate knowledge of geography, history, culture (e.g., celebrities, sports, movies) Ability to classify and categorize
Insight	Ability to see alternative explanations, others' points of view, locus of control (internal vs. external), defense mechanisms
Judgment	Sample questions: What would you do if. "you found a stamped envelope next to a mailbox" "a fire started in a theater" "you saw a man with big feet"

Children also usually have little idea of what occurs in a psychiatric assessment, and may fear being hospitalized, or otherwise punished, especially if their difficulties have been a source of recrimination in the family. A child who harbors a family secret or concerns about a parent's behavior may fear punishment, relocation, or loss of contact with that parent if he or she speaks openly. Other children only know they are being expected to articulate explanations for behaviors that may not make sense to them, let alone to adults.

TABLE 4.3.3

MINI-MENTAL STATUS EXAMINATION

		Score	Points
Orientation			
1. What is the	Year?	——	1
	Season?	——	1
	Date?	——	1
	Day?	——	1
	Month?	——	1
2. Where are we?	Country	——	1
	State or territory	——	1
	Town or city?	——	1
	Hospital or suburb?	——	1
	Floor or address?	——	1
Registration			
3. Name three objects, taking 1 s to say each. Then ask the patient all three after you have said them. (Tree, clock, boat, or body parts for children <7 yrs.) Give one point for each correct answer. Repeat the answers until patient learns all three.		——	3
Attention and Calculation			
4. Serial sevens. Give one point for each correct answer. Stop after five answers. For children <age 7, have them repeat 2–5 digit strings (e.g., "4–7," then 3–5–8," and score one point for each digit string repeated forward correctly).		——	5
5. Spell "world" backwards. For children <7, have them repeat 2–4 digit strings backwards (e.g., examiner says "5–2" and child repeats back "2–5," etc.).		——	5
Recall			
6. Ask for names of three objects learned in 3 above. Give one point for each correct answer.		——	3

Language		
7. Point to a pencil and a watch or to body parts. Have the patient name them as you point.	——	2
8. Have the patient repeat, “No ifs, ands, or buts.”	——	1
9. Have the patient follow a three-stage command. “Take a piece of paper in your right hand. Fold the paper in half. Put the paper on the floor.”	——	3
10. Have the patient read and obey the following: “CLOSE YOUR EYES.” (Write it in large letters.) For children <7, have them read their name.	——	1
11. Have the patient write a sentence of his or her choice. (The sentence should contain a subject and an object and should make sense. Ignore spelling errors when scoring.) For children <7, have them write their name.	——	1
12. Have the patient copy the design printed below. (Give one point if all sides and angles are preserved and if the intersecting sides form a diamond shape.) For children under age 7, have drawn a circle or oval.	——	1
TOTAL:	——	(24)

(From Ouvrier RA, Goldsmith RF, Ouvrier S, Williams IC: The value of the mini-mental state examination in childhood: a preliminary study. *J Child Neurol* 8:145–148, 1993, and Jain M, Passi GR: Assessment of a modified mini-mental scale for cognitive functions in children. *Indian Peds* 42:907–912, 2005, both with permission.)

Similarly, interested others (such as school staff or other health care providers) may have diverse (or unrealistic) expectations of what a psychiatric assessment can provide or how it might be implemented (such as a month-long inpatient observation).

In order to diminish unreasonable fears and to encourage more honest, accurate reporting, the clinician will seek, even prior to the first interview, to cultivate a partnership with the parents and interested others to support the child. A brief (under 15 minutes) initial phone call can help clarify how parents and teachers perceive the identified problem and introduce potential areas of exploration (e.g., specific patient strengths or interests) that may facilitate the family’s and child’s functioning and comfort with the assessment. If such calls are not possible or feasible, trained office staff may make these initial inquiries or request that the family completes a pre-intake survey prior to the initial appointment.

During this same initial phone contact, clarification of preferred contact numbers where the parents can be reached without embarrassment, billing information, and consent to speak with others familiar with the child can often be accomplished in advance of the actual interview. Some parents are reluctant to consent to contact between the clinician and others (such as the school) until they feel more comfortable with the clinician. Parental preferences for e-mail correspondence can also be discussed before the actual interview, so that efficient methods for data acquisition from others can be determined. Finally, special needs of the child (e.g., visual difficulties) can be discussed in a less embarrassing context than in front of the

patient. Similarly, ideas from the parents for making the assessment flow more comfortably, such as allowing the child to bring and demonstrate favored toys or electronics, or preferred discussion topics for teenagers, enhance the initial alliance, crucial in any later treatment efforts.

_____ 1. Child's Name: ______________________ Preferred Name: ______________________

_____ 2. Parents/Guardians: ______________________________

_____ 3. Contact Information:

Home Phone: ______________________ Cell Phone: ______________________

Billing Address: ______________________________________

____

_____ E-mail: ______________________________

_____ Interests (Sports, Music, Extracurricular): ______________________

_____ 11. Condentiality (HIPAA, e-mail) Discussed: ____________________________

FIGURE 4.3.1. Preparatory checklist for clinical assessment.

Initial Meeting

While circumstances may call for an alternative initial interview structure, it can be helpful to first meet together with parents and child, then separately with the child and the parents, and then bring everyone back together to wrap-up the meeting. When first meeting, depending on the reason for presentation, it may be helpful to start by eliciting strengths and future goals of the child. This can help build rapport and frame the interview toward a positive experience for the child and family (25).

Meeting with Child and Parents Together

The child and parents are often seen together at the beginning of the child psychiatric interview; this allows the clinician to make introductions, describe the purpose and structure of the assessment, begin to establish rapport and level of comfort, and discuss confidentiality so that parents and child understand what information will and will not be shared. Allowing the child to become sufficiently comfortable before parents depart can cultivate an environment where the child is less guarded. Children can often indicate an acceptable point for the parents to leave the room, usually within a matter of minutes, and transitional objects (from blankets to handheld computer game devices) may ease these transitions.

Confidentiality is one of the most challenging issues surrounding child psychiatric interviews, especially with adolescents who may be particularly concerned about who might hear what from the clinician. Parents and children should be informed of the confidential nature of the doctor–patient relationship so that the clinician is not seen as a parental spy. However, findings such as diagnoses often must be reported to parents, to insurance companies (for reimbursement), and to schools for classroom or curricular modifications to occur. Describing to the adolescent what will be told to specific others is usually sufficient, as well as what information will not be revealed. Parents and child should be told explicitly that confidentiality does *not* extend to situations that pose a clear danger to the child or others. In cases where this emerges (e.g., the child describes hoarding pills in a drawer to commit suicide or obtaining bullets to threaten a student at school), the clinician should clarify with the child how they will tell appropriate others, and ideally how the child will participate in the disclosure to others. State laws vary and change regarding what information must be shared or kept confidential between clinicians and patients, even minors, about substance use, pregnancy/abortion, and weapons possession, so clinicians should remain familiar with local legal standards of confidentiality. While treatment may not be possible with some children unless certain information remains confidential, confidentiality should not become collusion.

The Parent Interview

In the initial face-to-face parent interview, the clinician seeks to understand the parents' perspective on the problems leading to the referral. The clinician endeavors

to identify the "why now?" reasons that this evaluation is occurring, how parents understand the evolution of their child's symptoms, what current priorities each parent or other party (such as the school or court) describes for this evaluation, what impact the child's difficulties now have on the family, and how the child's symptoms impact his or her functioning with peers and at school or beyond (e.g., work, extracurricular activities). As noted earlier, throughout each component of the interview, the clinician remains alert to the potential functions or benefits the current symptoms carry for the child, the apparent attunement of the parents to the child's needs, and available resources; these resources include special skills or talents the child may possess and the presence of other individuals who exert a positive influence on this child. The clinician will also be attentive to any relevant cultural factors that may affect the child's symptoms. The goal is to obtain as full a picture as possible of the child's current developmental trajectory. Sample questions for eliciting each component of this interview are provided in Table 4.3.4.

The parent interview can be complicated by multiple factors, including parental ambivalence about having a child evaluated by a psychiatrist, by divergent perceptions among parents and adults about the origin of the child's problems, fears of loss of control or criticism, or parental shame or embarrassment about perceived parenting faults or personal past history. Just as the child's level of development will impact the content of the interview, so too do adults vary in their sophistication about parenting techniques or understanding their child's developmental needs. To understand parents' descriptions about the child in their proper context, the clinician will remain attentive throughout the interview to the parents' own vulnerabilities and concerns about parenting. Parents may have their own past experiences rekindled when they see their child in distress, and may seek to prevent outcomes they experienced (26). Clinicians may detect reflexive inclinations in some parents to revert, when stressed, to doing what their parents did to them, and clinicians may detect distressing parental recollections about their own childhood adversities brought back through their child's problems. Multiple techniques may be required for the clinician to help parents overcome such obstacles during the course of the interview.

The Child Interview

Inquiring what the child has been told or understands about the purpose of the interview often provides initial information on the child's experience of presenting to the clinic, the communication style between the child and parent(s), and the child's understanding of the circumstances. The child's description of what he or she has been told regarding the evaluation may further reveal the child's priorities for intervention.

In addition to the purpose of this evaluation generally, the clinician should inquire about what the child believes parents, teachers, or other adults want to be different as

a result of this interview. While the child may not know what others seek, this approach helps elucidate what the child recognizes about others' perspectives, and also facilitates the child projecting thoughts or fantasies about this evaluation.

The interviewer then focuses attention on gathering additional history from the child's point of view, paying particular attention to how the child attributes meaning to things. Although the reliability of information from the child on any given point will vary with the topic and with the individual child, the clinical information derived from direct observation of and interaction with the child is essential (27). The child's description of feelings, moods, levels of distress, and significant events contribute to a complete understanding of the child, and to matching and framing viable treatments with the individual child. In addition, symptoms such as compulsions, urges, obsessive or suicidal thoughts, hallucinations, tics, or a thought disorder may not be recognized or acknowledged by the adults in the child's life, and children are often more reliable reporters of internalizing symptoms such as anxiety (28). Similarly, the child may be the only informant with knowledge of traumatic events (e.g., sexual abuse of the child, bullying), delinquent acts, or the child's idiosyncratic interpretation of certain events.

TABLE 4.3.4

INTERVIEW: SAMPLE CLINICIAN QUESTIONS

Component	Description	Sample Questions for Caregiver	Sample Questions for Child
Reason for referral	Chief complaint/primary reason for presenting for evaluation	What are the primary concerns bringing you in today? Whose idea was it that [child] might need this evaluation? Who is most concerned about [child's] behavior? Has anyone else, such as other family members, school staff, or other agencies, encouraged this evaluation? What do you/they hope this evaluation will accomplish?	What is your understanding of why you are here today? [What did your parent(s) tell you about coming here today?] Who wanted you to meet with me today? Why do you think they want us to meet? What do you think they are worried about? What do you think/feel about being here?
History of problems/present illness	Why now: narrative about events leading to current presentation [open ended questions]	When did you first notice concerns about [child]? How did the problem develop over time? Have there been times when things have gotten much better or worse?	What is not going so well for you? What do you wish would be different? When was the last time you remember things going pretty well? What do you think is making it such a hard time?
	Functional	How do you understand	When/Where do you notice

assessment of problem behaviors	[child's] behavior? When/Where does the problem occur most often? How does the problem impact [child] at home? At school? With peers? Is the problem behavior worse in one of these places? What usually occurs right before [problem behavior]? What happens after [child] does [problem behavior]? Does anything make the behavior worse/better?	having a hard time? [triggers] What happens when you [exhibit symptoms]? How does your [parent, teacher, friend] respond when you [exhibit symptom]? How do you feel after you [exhibit symptom]?
Daily routine	Please walk through what an average day looks like for [child], starting from waking up in the morning and going through waking up the next morning? How about over the weekend?	Let's walk through a typical day for you. What time do you normally wake up …
Past problems	Has [child] experienced problems in the past that have caused concern? Have things escalated to this point in the past?	Do you remember ever feeling this badly when you were younger? Was there anything you can remember that helped make things feel better?
Comorbid symptoms (Psychiatric review of systems): Basic functioning: Sleeping Eating Physical activity Self-care DSM-5 diagnostic criteria screening [Substance abuse and trauma assessed separately]	Does [child] have any other symptoms that are concerning and/or interfere at home, school, or with friends? Basic functioning: Let's talk about some of the essentials for staying healthy: How does [child] sleep at night? Does [child] take naps during the day? How has [child's] appetite been? Has [child] ever been under/overweight? How often does [child] get physical activity? How much prompting does [child] require to take care of everyday tasks such as brushing teeth, showering, getting dressed? DSM-5 diagnostic criteria	Is there anything else going on that you wish were different? Is there anything else that is bothering you? Basic functioning: Do you have any trouble falling asleep? Staying asleep? What are your favorite foods to eat? Are you usually hungry for breakfast, lunch, and dinner? Snacks? Do you feel like you have enough energy during the day or do you usually feel tired? How much exercise are you getting? Is it pretty easy or hard to get active?

		e.g., ADHD, Anxiety Disorders, OCD, Depression, Bipolar disorder, Psychosis, Eating disorder, Conduct Disorder, Oppositional Defiant Disorder, Anger/Aggression	
	Substance use	How is drug/alcohol use discussed in the family? Has [child] done anything to suggest use of alcohol and/or drugs? Have you detected [child] to be drunk/high? Have you seen or found any drug paraphernalia that might be [child's]? Has [child] spoken about drinking, smoking, or drug use? How about his/her friends?	Have you ever been around any drugs or alcohol? How harmful (or not) do you think it is to drink, smoke marijuana, use drugs, etc.? Have you ever tried cigarettes? Alcohol? Drugs? How often do your friends drink/use? Have you ever been high/drunk? Has that ever led to problems for you? [If positive use] What do you notice when you use [substance used]? It is helpful in any way?
Safety assessment	Suicidal ideation, prior suicide attempts, future orientation Homicidal ideation, agitation, aggression Access to guns, history of stealing/legal involvement, running away, fire setting Risky behaviors (e.g., promiscuity, restrictive eating, substance use)	Has [child] ever talked about wanting to die? Has [child] ever talked about hurting himself? Others? Has [child] ever done things to hurt himself? To hurt other people or animals? Has [child] ever been involved with school officials or police because of threats or harm toward others? Does [child] tend to be on the more cautious or risk-taking end of the spectrum? Have you noticed that [child] tends to be impulsive?	Have you ever thought about not wanting to be alive anymore? Have you ever thought about hurting yourself? Others? Have you ever done something to hurt yourself? What was the purpose? How did you feel after you did _____? Have you ever hurt anyone else on purpose? How did you feel about that? How do you feel about that now?
Previous testing and treatments	Prior diagnoses Prior treatments and efficacy (including outpatient, ER visit, and inpatient hospitalizations) Independent neuropsychological testing, academic or SPED testing via school, etc.	Has [child] received any diagnoses or treatment(s) in the past for emotional or behavioral concerns? Has [child] undergone any testing through school or independent entities?	

Develop-mental history	Bodily/basic function	How did toilet training progress with [child]? Has [child] had periods of wetting or soiling?	
	Motor development	When did [child] start walking? Have concerns been raised about [child's] handwriting? In what sports/activities has [child] participated? Which ones have gone well? Not so well?	Which sports do you like to do? Which ones are harder? Do you have any problems playing games/sports/ music /dancing?
	Cognitive development	When did [child] begin preschool/school? How did that go? How does [child] do with reading? Math? Writing? In which subjects does [child] do particularly well? Which subjects are more difficult?	
	Interpersonal development	How did [child] relate to you as an infant/toddler? As a toddler, did [child] show interest in things you pointed to? Did [child] point things out to you? How did [child] respond to your requests or directions? When did [child] start interacting with other children? How did that go? Did [child] have any significant attachments or relationships to others that ended? What kind of friends does [child] have at this point? How does [child] get along with these children? Does [child] get invited to play dates, birthday parties, sleepovers?	How do you get along with the other kids in your class? With your teacher? Who are some of your good friends now (when/where met, what do together, how often)? How often do you and play together? How long do you stay at [friend's house]? Do you spend the night at [friend's house]? How does that go (What do you do?) Any rough spots between you and other kids? How come? Have you lost any good friends (because of moves, misunderstandings)?
	Emotional development	Does [child] recognize when he or she is sad, happy, etc.? How does [child] soothe him/herself when unhappy or in a bad mood? What is the child's	How often do you feel sad? Mad? Worried? Happy? Does anything in particular make you sad/mad/worried? What do you do when you are feeling that way? How do you calm yourself

		prevailing/most common mood? How does the child respond to unexpected changes? Disappointments? Frustrations? Worries?	down when you're upset?
	Moral development	Does [child] recognize right from wrong? Does [child] describe any "principles" that guide his/her actions? How does [child] contend with mistakes or when confronted about doing something wrong? Has [child] ever deliberately hurt any animals or other kids? Bullied or been bullied by other kids? Does [child] show remorse after hurting someone? Does [child] consider consequences of decisions on others? Is [child] either too perfectionistic or morally rigid?	Do you ever do things that you wish you hadn't? Do you ever hurt others? Even if it's not on purpose? What do you wish will happen when you [hit other, say something really mean, break/steal someone's toy]? What does happen when you do something that hurts or upsets [someone else]? Can you keep yourself from hitting/getting back at someone if you want to?
Trauma history		Has [child] ever been hurt/injured? Has [child] ever witnessed anything really bad or frightening or been traumatized? Has [child] described frightening dreams/nightmares? Have you [parent] had any traumatic experiences that remind you of what [child] is going through?	Have you ever been hurt? Injured? Have you ever seen anything really bad? Frightening? Have you ever seen anyone get hurt badly? Do you ever have scary dreams or nightmares? Do you ever see or hear something that reminds you of something really scary? Who did/would you tell if someone tried to hurt you?
Family history	Family conflict, differences in parenting style	Do [parents] agree on how to respond to [child]? Is there anything [one parent] does quite differently from [other parent], or from your own parents?	Do your parents tend to agree on how to help you? Punishment and discipline? How have your symptoms affected your family?
	Developmentally sensitive parenting challenges	Do you treat [child] differently from how you were treated by your parents?	

		Did [parents] grow up in similar type families?	
	Familial/genetic contributions: Mental illness Learning disabilities Notable medical illness Completed suicide Response to medications Anyone who presented similar to child?	Has anyone on father's (mother's) side of the family had depression, anxiety, … ? Has anyone in the family had serious medical problems? Has anyone in the family ever been psychiatrically or medically hospitalized? Incarcerated? [If relevant] what was that like for [the child]? What do you think [child] has inherited from [all parents, biologic, and adoptive] ?	Are you like anyone else in your family? Do you know if anyone in your family has ever felt like you do?
	Family constellation	What were the circumstances surrounding the conception and pregnancy with [child]? Have there been any times when [child's parents] were separated/together? Have any changes in the family [loss/addition of parent, loss/addition of sibling or other in the home] contributed to [child's] symptoms? What kind of contact does [child] have with [parents, grandparents, primary caregiving relatives]? What does [child] say about [other parent, caregivers?]	Who lives at home? How does everyone at home get along? How do your parents understand you? Have either of your parents ever been away very long? Doe you miss anyone from your family? With whom do you get along best in your home? With whom do you have the hardest time? Why?
Medical history	Name and contact of pediatrician Most recent physical exam, blood work/labs, imaging Active medical problems Past medical problems, including history of head injuries, loss of consciousness, seizures, medical work-ups Prior medical	Has [child] ever had any medical illnesses or serious injuries? Been hospitalized? Had any operations? Was [child] physically ill before these symptoms started? Has [child] had any physical symptoms that occur with/since the emotional symptoms?	Have you ever been really sick? Have you ever had to go to the hospital (what happened?) Have you ever had any surgeries (what was that like)? Have you been physically sick since you have had problems with_____?

	hospitalizations, surgeries		
Medications and allergies	Include efficacy, tolerability, and compliance: Current Past Allergies or adverse reactions	[Walk through medication treatment history] How is [child] with taking medications? Do you have any concerns about the medications? What is your sense of how helpful (or not) the current regimen is? Has [child] ever been allergic to anything?	What's your understanding of why you're taking medications? Have they been helpful? Have you had any side effects?
Educational history	School functioning, including type of school, grade, attendance, accommodations, social connection, strongest and weakest classes, etc. Extracurricular activities and level of mastery and engagement Future orientation (e.g., what do you want to be when you grow up?)	How did [child] do each year in school? Did [child] ever receive any special educational services? Has [child] ever been suspended, expelled, or asked to leave as school? Did [child] ever have any periods of excessive absences? Did [child] ever fail in subjects or grades? Has [child] even had any summer school or after-school tutoring? Is there anything [child] particularly enjoys or does well at in school?	Which subjects do you like best at school? Is the academic work at school reasonable, or too hard or fast? Is there anything you have trouble understanding at school? Has anyone ever helped you with school work? What do they do? Is there anything that would make being in class easier? Who do you sit with at lunch? What do you do at recess?
Strengths and supports	Areas of strength and interest	What is [child] good at? What does [child] do for fun? What does [child] do during the day? What does [child] want to do/wish he could do?	What do you most like to do? What are you really good at? What do your friends/other students think you are really good at? What would you like to be better at? Do you feel special in any way? What do you want to do when you grow up?
	Community and environmental supports	What is your neighborhood like? Do kids play outside much in your neighborhood? Any neighborhood problems or tensions? Is a language other than English spoken at home? If so, by whom, and does [child] also speak/understand that	Outside of your home, where are you most happy? Are there any other adults who are special to you/work with you? Can you tell me about your best friends? Are there any kids that bother you or make you uncomfortable?

	language? [If family is of recent immigrant origins], does [the child] still have close relatives there? Does [child] visit there often? What is the family's religious tradition? Does [the child] attend services regularly or have strong religious identifications? What activities does [child] participate in? Are there others who work with [child]? Do you have any help/support managing these problems with [child]? How do your family members view [child's problems]? Does [child] benefit from interactions/participation with neighbors/scouting/hobbies/shared interests with others?	Is there a group you feel a part of? Who do you "hang out" with? Is there a group you would rather be a part of? Are there particular others you'd like to hang out with? Is there any place you really like to go to feel better?
Media diet	What does [child] watch/read/listen to? How much time does [child] spend on social media? Video games? Watching television/movies? Listening to music? Reading? How does media (e.g., social media, television) influence [child]? What effects do you think [child's] musical choices have on him?	How much time do you spend on electronics every day—social media, video games, TV, listening to music? What about [TV show, music, magazine] most appeals to you? How do you feel after watching/listening/reading ____? Do you ever get into trouble after watching/listening/reading ____? Which apps do you use? What appeals to you about them? What are your go-to social media platforms, and how often are you on them? How do you decide what you post on social media?

For the psychiatric interview of the child to yield accurate, clinically useful information, the interview process and wording of questions must be tailored to fit with the child's understanding (29). The child may simply not understand what the

interviewer is seeking, or comprehend terms necessary to answer the questions accurately. In addition, the interviewer must be attuned to the child's efforts with current developmental tasks. The child may provide misleading answers to shield other family members, to protect self-esteem against acknowledging some perceived failing, or to avoid changes even in painful circumstances if the child fears it will entail unwanted change. The adolescent may not trust the interviewer and may provide evasive or misleading answers for fear that the clinician will see him or her as "weird" or "crazy" or might collude with the parents against the teen.

The Adolescent Interview

Adolescents sometimes require additional modifications for this interview (30). First, adolescents sometimes fear parents will skew the interview by getting to tell their "version" first, and the clinician, as an adult, will side with the parents against the adolescent. To prevent this, the clinician may want to speak over the phone initially with the parent about their concerns and about any information they consider important for the clinician to know prior to meeting with the adolescent. This also affords an opportunity for parents to identify information they have not yet shared with the adolescent (e.g., finding drug paraphernalia in the adolescent's room, previous marriages of parents). Meeting briefly for a few minutes with the parent and adolescent to clarify objectives and the format of the evaluation, and then meeting with the adolescent alone at length is more likely to enhance an alliance with an adolescent. Clarifying during this initial segment that the clinician and the parents will later meet alone to review birth history, developmental milestones, and family history usually is acceptable to adolescents.

Adolescents may articulate that they do not want to participate in this evaluation or may resist answering questions. In such situations, the clinician may first validate the adolescent's reluctance to talk about personal matters with an unknown individual and then attempt to encourage the adolescent's cooperation by trying to identify goals the adolescent may wish to be advanced by the assessment and siding with those. For example, the adolescent may respond to clinician efforts to help identify what the adolescent needs to do to satisfy parents so that the adolescent no longer needs to see a psychiatrist. In addition, clinicians can decrease resistance by beginning the history taking by inquiring first about the adolescent's interests, strengths, and musical/athletic preferences, rather than a too-exclusive focus on "problems." Adolescents are often exquisitely sensitive to feeling that they are being perceived or judged as vulnerable, "weird," or "different" from peers; hence it is generally best to begin with strengths before introducing areas of difficulty. In the same spirit, it is best to try to use lay terms, rather than technical terms or those laden with implications of pathology or transgression.

DEVELOPMENTALLY SENSITIVE TECHNIQUES FOR THE

DEVELOPMENTALLY SENSITIVE TECHNIQUES FOR THE PSYCHIATRIC INTERVIEW

The choice of developmentally appropriate techniques to elicit information from children and adolescents is not strictly dictated by chronologic age. As part of their presenting difficulties, some children may have delayed or aberrant development in some realms that impact the conduct of the interview, such as social language. For other children, regression in the face of stress or anxiety may lead to refusal to speak, oppositionality, tantrums, or retreating to other immature behaviors, either in the context of the interview or as an aspect of the child's more general functioning. Distressing content may similarly require interviewer techniques (drawing, puppets, or play) ordinarily used for younger patients. With some children, once they are at ease with the interview situation, more explicit discussion may be able to take the place of play. The optimal combination of techniques most likely to place the child at ease and to obtain useful information will depend on where a given child is on the developmental (cognitive, emotional, interpersonal) spectrum. The choice and timing of techniques further depend on the emotional valence or difficulty of the issue being addressed, and the fluctuations in the rapport between the child and the clinician. In child psychiatric interviews, the clinician continuously monitors the usefulness of a technique at a particular moment and shifts between techniques as the interview unfolds, according to the waxing or waning of the child's anxiety, trust, and engagement.

Four categories of techniques are generally employed in the child psychiatric interview. First, *engagement* techniques are often required to help put the child at ease and elicit the child's willingness to actively participate in the psychiatric interview so that the child will provide accurate and meaningful clinical information. Second, *projective* techniques are used to allow the child to reveal underlying themes or issues which the child may be unable to verbalize directly and to assess the child's unique ways of thinking and responding to stimuli. Third, *direct questioning* techniques are required to clarify particular points or elicit specific information needed to distinguish disorders, contributions to the child's problems, and intervention options. Fourth, *interactive* techniques are needed to clarify how the child relates to, as well as accepts or integrates input from, others. Throughout the psychiatric interview, opportunities for the child to express content in his or her own way must be balanced with the clinician retaining enough control of the interview to ensure sufficient information is obtained to allow effective clinical assessments and treatment planning.

Techniques to Engage the Child

Engaging the child can be challenging, particularly since the child is in an unfamiliar

setting with unfamiliar adults involved in an unfamiliar task. Accordingly, making the setting and tasks more familiar often helps put the child at ease and accelerates engagement. To make the setting more attractive, many child psychiatri sts will provide toys in both the waiting room and clinical office. In addition, child-friendly art or even movie posters may simultaneously make the setting more appealing and provide a stimulus for the child to describe reactions to the poster, characters, or movie preferences that may provide important information about the child's underlying concerns or perceptions. Similarly, toy figures, puppets, and similar relationship-oriented toys may ease the child into the interview. Generic toy figures are usually preferable, since they are more likely to evoke the child's specific themes and concerns rather than the prefabricated scripts associated with specific toy characters based on TV shows or movies. Tasks that are framed as games or that involve activities (drawing a house or family) familiar to the child often help the child transition into the psychiatric interview.

In addition to making the child feel comfortable, engagement techniques facilitate the child's presentation of information. Imaginative play with puppets, toys, or the interviewer provides useful inferential material about the child's concerns, perceptions, and characteristic modes of regulating affect, impulses, and transitions. By allowing the child to direct the content, the interviewer can follow the sequence of the child's concerns, note themes that emerge, and observe the points at which a child backs away from the story line, shifts to a new activity or topic, or falls into a repetitive loop. The form of the child's play further provides mental status information about the child's coordination and motor skills, speech and language development, attention span, readiness to engage the interviewer, capacity for complex thought, and affective state. Absence of imaginative play or concrete, repetitive, noninteractive play, for example, may suggest autism spectrum disorder.

Adolescents can be difficult to engage. Efforts to indicate familiarity with contemporary adolescent tastes (music, movies, terms) can be perceived as disingenuous by the adolescent. Instead, clinicians may engage the adolescent by inquiring about current interests, musical preferences, and adherence to current adolescent values, but from a curious, "just help me understand it" perspective, rather than from one of "trying to be hip." Adolescents often are ambivalent about the talking relationship, so fidget toys (squeeze balls, modeling clay, finger cuffs, cards) allow a socially acceptable option for keeping their hands busy during the interview and make the interview feel less like an interrogation. Complex games, such as chess or video games, require such focus that the interview may become subordinate to the game itself, impeding the clinical interview.

Concern about judgment can limit how vulnerable a child is willing to be with a clinician. It can be helpful for the clinician to maintain a goal of figuring out what is compelling/likeable about the child to help create a genuine interest in and connection with the child. Sometimes, the clinician is in the position of holding hope

until the child can regain hope that things can get better, so finding ways to genuinely portray interest can improve patient engagement and alliance.

Projective Techniques

In addition to imaginative play, projective techniques may help the child express concerns indirectly, so that anxiety about significant fears, telling family secrets, or betraying loyalties is minimized. Among the most common projective techniques is picture drawing. Commonly, the child is asked to draw a picture of him/herself or family doing something. By complimenting the picture close to its completion and expressing curiosity about what is happening in the drawing, the clinician can help ensure that the content of the picture, rather than its artistic quality, remains the focus of the interview. For pictures of the child, body details including sizes of appendages or body parts (e.g., fingers, toes), relative size of the figure to the page, and frequent erasures can all reveal underlying issues of anxiety, perceived agency to address difficulties, or needs to control the environment. Depictions of the self as nonhuman, grotesque, imbued with super powers, or of the opposite gender may provide clues about the child's self-image and underlying wishes. The relative size and placement or omission of family members in a family drawing may illuminate the child's feelings about family relationships. Aggressive or sexual themes may be revealed more readily in drawings than in words.

Verbal projective techniques can similarly yield important information. Asking what animal or character (TV/movie star, cartoon, superhero) the child would most like to be, or whom the child would take along to a deserted island, or asking what the child would do with three magic wishes often allow underlying issues to emerge. For example, children may describe wishes to be dominant predator animals to avoid being harmed, or to be gentle animals so that their rage might become less of a problem. Wishes may reveal basic needs, such as food or a safe place to live, or longings for parents to reunite or for the return of a departed friend. Wishes sometimes reveal specific desires, such as "not to have tics anymore," or "never to get teased." Very general or altruistic wishes, such as "world peace" or "to live in a big house with lots of money" warrant further exploration, such as "Are there particular fights you would especially like to stop?" or "Who else would live there?" and "What would you do first with lots of money?"

Open-ended interactive techniques require the child to respond to changes introduced by the clinician. The squiggle game described by Winnicott (31) consists of the clinician drawing a "squiggle," or curvy line, and asking the child to turn it into a picture of something. The resulting picture can then be described and discussed between the child and clinician. The child may also produce a squiggle for the clinician to develop, and the clinician can draw pictures of subjects or topics suspected significant to the child. In addition, incomplete, affectively evocative

beginnings of stories or fables can be described to the child, who then elaborates or completes the story (1).

Projective techniques may help adolescents to reveal and share emotionally significant concerns with the clinician despite the developmentally expectable suppression of fantasy in favor of more realistic discourse and reluctance to reveal vulnerabilities or anxieties to adults. Inquiries into favorite, or most disliked, movies, television characters, political or historical figures, musicians or artists, or sports figures all allow elaboration of the teenager's ideas (and ideals) in displacement. The more the adolescent resists direct discussion of his or her own concerns, the greater the displacement that may be required between the projective figure and the adolescent's real life. For example, adolescents less distrustful of the clinician may readily speak about their own social longings or anxieties regarding friends at school, while those adolescents more suspicious of the clinician's motives or wary of self-revelation may be more likely to reveal personal concerns or feelings as projected on or embodied in celebrities or other characters distant from the adolescent's real life. Adolescent resistances are often revealed by reluctance to divulge names of friends, or even questions about why the clinician needs to know this information. If resistance is detected, questions about what the adolescent most admires about a character, or what the adolescent imagines this character would do in given situations, may reveal the adolescent's perceptions or repertoire of response options through projection onto the character.

Since one of the developmental tasks of the adolescent is to find a place among peers, the vicissitudes of joining, rejecting, or being rebuffed by various groups of peers is an essential part of the adolescent's process of social self-definition. Amidst this preoccupation with ingrouping/outgrouping, adolescents are very sensitive to being included or excluded, and issues of fairness, justice, and revenge arise. Asking the adolescent about the different cliques or groups at school and his or her relationship to them provides useful information about the teen's self-image. Similarly, questions about what the adolescent sees as fair or not fair and what he or she would most like to change about his or her school or the world often reveals underlying concerns and issues.

Older adolescents may be able to respond to second-order or circular questions about what others think someone else's motives or thoughts were. For example, the clinician might ask what the adolescent thinks his best friend was thinking when the friend skipped school. Again, if the adolescent finds a topic too emotionally charged or fears betraying a peer, the clinician may need to ask about those more distant. For example, the clinician might ask what the adolescent thought a celebrity or movie character was thinking or trying to accomplish (motive) when the movie star made certain comments or engaged in certain behaviors.

Additional projective techniques are appropriate for all age levels and provide another vehicle to elicit significant information unique to that child. Asking the child

or adolescent about favorite books, magazines, music, television shows, movies, or video games may provide important information and help cultivate bonds of common interest between the child and clinician. Particularly if the evaluation is to extend over multiple sessions, or if treatment with the clinician is anticipated, the clinician's exploration of the child's preferred media may help convey interest in the child's world, as well as help illuminate important concerns on the child's part. While the clinician has to be careful not to impose ideas or judgments of characters important to the child, such figures often provide a vehicle or mechanism for discussing difficult content.

Direct Questioning

The goal of direct questioning is to clarify the presence or chronology of symptoms or events, to explore how the child sees the world and functions within it, and to follow up on themes suggested by the history or through play and other interactions with the clinician. Direct questioning can help fill in gaps not revealed by the child, and may help focus attention if responses become circumstantial or tangential. Direct questions may seem to benefit clinician needs more than the concerns of the child, so children may resist answering direct questions, particularly if the child imputes a critical or intrusive intent to the question or an effort to label him or her in some way as crazy, weird, or otherwise deviant. Tact, timing, and the phrasing of the question; appreciation of the child's cognitive and linguistic development; and regard for the impact of the question on the child's self-esteem all influence the effort the child will make to respond to a direct question. In addition, the structure of the question will markedly affect the quality of the child's response.

Questions that allow the child control of the depth of the response are usually preferred early in the interview, and more focused questions can be employed later as needed. Asking the child to describe friends ("Tell me about your best friend"), siblings, or parents, is preferable to "Do you get along with your brother?" which may invite only a "yes" or "no" response. Open-ended questions such as "What sorts of things make you mad/afraid/happy?" and "What do you daydream about?" are similarly preferable to "Do you get mad?" or "Do you ever daydream?" Early in the interview, less anxiety-provoking questions are preferred ("What is your school like?"), as momentum can be generated for the more difficult questions about family relationships or why others are distressed by the child's symptoms or behaviors.

For younger children, anchoring direct questions chronologically to major events may help children provide more accurate answers. For example, "Did that happen before or after your birthday?" or "How has that (problem) been since school ended?" allow greater precision by the respondent. At the same time, direct questions should continue to elicit feelings rather than "just the facts," since the child's affective narrative history is usually more important than the actual chronicle of

events.

Similarly, direct questioning in adolescents may require particular tact and attention to positives or strengths before questions about the adolescent's negative behaviors can be addressed. For example, inquiries into the adolescent's best school subjects or what avocations the adolescent is good at may need to occur before inquiries about troublesome school subjects, or the adolescent's current problems. "No fault" phrasing of sensitive questions can help diffuse defensiveness on teens' parts. For example, "Are there ever any rough spots between you and other kids?" is a preferable starting point for inquiring about social difficulties rather than "Do you ever have trouble getting along with other kids?" Asking about future aspirations ("What would you like to do once you've finished with school?") also often provides a useful window into the adolescent's ideals, interests, quality of self-appraisal, and degree of identification with his or her family's values.

Substance abuse, sexuality, and risky behaviors are, by necessity, often assessed through direct questions. However, more general questions initially may make these topics more comfortable and thus the information obtained more accurate. The clinician can often use a simple question, such as "What's your take on drugs and alcohol?" that allow substantial latitude, and then focus in further, contingent on the child's responses. For example, the clinician may hear "No, I don't do any of that anymore," which could then be followed by "What led to that decision?" and then proceed backward to when and what substances were used. Similarly, sexuality can be assessed by gentle direct questions such as "Have you ever had romantic feelings toward another (or liked someone as more than a friend)? How did that go?" (instead of "Have you had a boyfriend yet?"). Children and adolescents are often very cautious about discussing sexual urges, even more so if they fear the interviewer will be disapproving; hence, nongender-specific grammar is useful initially ("romantic feelings toward anyone" rather "Are there any girls you like?") (1) to indicate, at least implicitly, that one is open to hearing about homoerotic, as well as heterosexual, attractions. Finally, direct inquiries into risky behaviors (stealing, vandalism, assaults, gambling) often require general questions such as "Have you done anything that you now look back on and think 'that was pretty dangerous'?" "Have you ever done anything that would have gotten you in trouble if your parents or other grownups knew about it?" before proceeding to specific questions ("Have you ever stolen anything? Have you ever been beat up? Beat up someone else?"). Suicidal risk behaviors may be minimized or trivialized, particularly in adolescents, so additional questions to examine the adolescent's historical "genogram" of connections to others, fantasies about impacts of the suicide on family and friends, and value contradictions may be needed to clarify suicidality risks (32).

Interactive Techniques

During the interview, the clinician is uniquely positioned to observe firsthand how the child relates to another person and what feelings or reactions this elicits. How the child initially reacts to a new person, how the child sustains interaction throughout the interview, and how the child terminates the interview often reveal patterns important in the child's larger social life. Social rules of conduct, forced transitions, and game playing all allow the clinician to evaluate the child's ways of relating to others. The clinician can employ normal social conventions such as smiling, bending down to the child's level to obtain eye contact, and offering to shake hands to discern the child's initial reactions to unfamiliar others. The clinician can assess how the child negotiates social situations even in small interactions such as determining who will sit in which chair. The clinician can evaluate more complex social interactions during transitions ("It's time to put these toys up in the box.") and during games. Short games (tic tac toe) are useful since the clinician can quickly detect how the child responds to winning, tying, and losing.

Adolescents rely on more complex patterns of relating, often specific to a subgroup to which they now belong. For example, dress or language may be imbued with special meaning within adolescent subgroups, so clarifying what clothing symbols represent, idiosyncratic meanings of confusing terms, and values espoused by any identified subgroup the adolescent appears to embrace can all clarify the adolescent's patterns of relating and values. For example, an adolescent may wear a shirt with Bob Marley's picture on it, and inquiry may reveal the adolescent's commitment to equality. Similarly, the child may describe being "Goth," "punk," "straight-edge," "hip-hop," or other terms. Rather than attempting to be "with it" or assuming one knows what these imply to the patient, it is helpful to inquire what that term or ethos means to this adolescent. In addition, the adolescent may employ gestures or language ordinarily offensive or off-putting to the clinician. The clinician should observe whether these appear to be efforts to provoke the clinician, to titrate space between the clinician and the adolescent, or to be the adolescent's customary idiom, which the adolescent may not realize alienates others.

CONCLUDING THE INTERVIEW

Allowing the interview to end in a collaborative fashion increases the likelihood that the child will feel positive about the interview and any subsequent encounters with clinicians, including other evaluations or treatments. The clinician may wind up the interview by empowering the child with some degree of ownership of this interview. Questions which turn the interview topics over to the child such as "Are there other things that would be important for me to know about you or how things have been for you?" or "What else have I not asked about that is important?" facilitate this process. Similarly, questions such as "I've asked you lots of questions—do you have any questions for me?" demonstrate respect for the child.

The child may be curious about what the clinician thinks about the child and with whom the clinician will share findings. Most often, the clinical interview is but one piece of a larger evaluation, so the clinician may need to clarify that additional laboratory or paper–pencil testing, conversations with teachers or family members, or additional meetings may be needed for the clinician to have a fuller or more accurate impression. Discussing findings (including treatment recommendations) with parents first before discussing them with the child is usually advisable so that additional conflict is not generated if parents should disagree with the clinician's conclusions or resist certain suggested interventions (medication, individual therapy, changes in school placement).

LABORATORY EVALUATION IN THE CHILD PSYCHIATRIC EVALUATION

New techniques of molecular genetics, neurobiology, functional and structural imaging, and neuroendocrinology are deepening our understanding about the pathogenesis and biologic underpinnings of developmental psychopathology. Still, at this time, few, if any, definitive clinical tests exist to identify specific child psychiatric disorders. In the child psychiatry evaluation, laboratory testing remains a vehicle to identify a small number of specific etiologies of certain psychiatric symptoms, as suggested by history or physical findings that warrant such testing, rather than a widely applicable method of screening for specific psychiatric disorders.

Pediatric Collaboration in the Laboratory Evaluation

Close collaboration with the child's pediatrician or primary care provider remains important throughout the child psychiatry evaluation. These providers are familiar with the child's medical and developmental trajectory, as well as family background, and are often positioned to provide essential input on the emergence or progression of a child's symptoms. In addition, the pediatrician or other primary care provider may serve as an invaluable collaborator in the child's ongoing care.

The pediatric examination is a useful complement to the child psychiatric evaluation. The pediatric review of systems may clarify physical changes important in the evolution of the child's symptoms. In addition, growth charts may reveal changes in head circumference relevant to autism spectrum disorder, abnormalities in weight suggestive of an eating disorder or failure to thrive, or changes in stature relevant to hormonal changes. Similarly, the pediatric physical examination may identify visual or hearing problems that explain learning, language, social, attentional, or oppositional problems, as well as pubertal precocity or delays which

have important psychosocial consequences. The pediatric examination may also reveal emerging complications associated with treatment (such as weight gain or metabolic dysregulation associated with atypical antipsychotic use). The pediatrician may also identify congenital anomalies or other developmental physical features suggestive of specific developmental disorders or other medical disorders accompanied by psychiatric symptoms.

Collaboration with the primary pediatric care provider may help guide decisions about possible further medical consultations (e.g., audiometric, genetic, neurologic, speech) or other diagnostic tests (e.g., blood tests, electroencephalograms, neuroimaging, sleep studies).

Testing in Specific Childhood Disorders

Laboratory evaluation is warranted when other history or physical findings suggest a particular potential medical diagnosis, such as hyperthyroidism. Routine use of laboratory testing yields findings which alter the working diagnosis in approximately 1% of cases, and the yield for laboratory abnormalities, without the presence of other supportive signs or symptoms, remains less than 5% (33). Laboratory tests commonly considered in key forms of child psychopathology, particularly when other symptoms accompany the psychiatric symptoms, are summarized in Table 4.3.5; the interested reader is also referred to the related chapters elsewhere in this volume for additional details. More specialized technologies, such as positron emission tomography (PET), single-photon emission computerized tomography (SPECT), functional MRI (fMRI), and brain electrical activity mapping (BEAM) remain attractive research tools, but currently have no routine clinical or diagnostic usefulness in child and adolescent psychiatric populations.

TABLE 4.3.5

LABORATORY TESTING TO CONSIDER FOR PSYCHIATRIC DISORDERS

Disorder	Testing
ADHD	• Consider lead level if reason for concern
Anxiety disorder	• Consider thyroid function test (TFT), complete blood count (CBC), basic metabolic profile (BMP)
Autism spectrum disorder	• Consider workup to identify comorbid conditions important for treatment or genetic counseling, e.g., Fragile X, Angelman syndrome, and tuberous sclerosis complex • Consider EEG to detect possible comorbid seizures
Depression/Mood disorder (24)	• Consider CBC, BMP, TFT, vitamin B12, vitamin D, folate, urinalysis, toxicology screen • Also consider infectious etiology per clinical history, e.g., mononucleosis, Lyme, HIV
Anorexia	• Comprehensive metabolic profile (CMP), calcium, magnesium, phosphorous, CBC including differential (anemia, leukopenia, thrombocytopenia), TFT, vitamin B12, vitamin D, internationalized normalized ratio (INR)

	• Urinalysis for specific gravity (hydration status) • EKG +/− fuller cardiac evaluation as indicated • Consider bone density test
Bulimia	• CMP, calcium, magnesium, phosphorous, CBC, urinalysis • Consider EKG

OCD and related disorders (34)	If abrupt, dramatic onset of symptoms consider: PANS (pediatric acute-onset neuropsychiatric syndrome) or PANDAS (pediatric autoimmune neuropsychiatric disorders associated with strep infections)
	• CBC with manual differential, CMP, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP)
	• Urinalysis; clean-catch urine culture for those with pyuria
	• (PANDAS) Confirm group A beta-hemolytic streptococcal bacteria (GAS) infection via
	  ◦ throat or skin culture or rapid antigen detection test for GAS at the beginning of a PANDAS exacerbation (follow-up culture if the test is negative) or
	  ◦ clinically significant rise in antistreptococcal antibody (anti-DNase B (ADB) and antistreptolysin O (ASO)) between the onset of symptoms and 4–8 wks later.

Psychosis (35)	• CBC, CMP, calcium and phosphorus, TFT, ESR, antinuclear antibodies, ceruloplasmin, HIV screening, FTA-Abs for syphilis (strongly recommended. *RPR not sufficient*), vitamin B12 • Urinalysis, urine drug screen • MRI to rule out demyelinating disease, brain tumor (e.g. meningioma) • EEG to rule out a seizure disorder

APPENDIX 4.3.1

SAMPLE LETTER FOR PARENTS DESCRIBING THE CHILD PSYCHIATRIC ASSESSMENT

Dear [Parent],

We look forward to seeing [child's name] on [date]. This assessment will last approximately [time allotted]. Unless your child is very young, or uncomfortable separating from you, usually [clinician's name] will meet briefly with the parent or adults alone to understand their primary concerns, to obtain relevant medical and family history, and to review any sensitive information important to the assessment, but which may not have been discussed with your child. Bringing toys or activities (books, mazes) to occupy your child during this part of the assessment can be helpful in making him or her comfortable. Report cards, reports from school, prior clinicians, or others involved in the child's care (daycare, courts), or educational or psychological testing reports can be very helpful, so we encourage you to bring these.

[Clinician's name] will usually then meet with your child alone for [allocated time], as well as, perhaps, with all of you together. This interview will include questions about how he or she interacts with friends, parents, and teachers; your child does not need to prepare for this interview. [Clinician's name] may measure your child's height, weight, and pulse and blood pressure, but the child will not need to change clothes or to expect to be examined like during a pediatric visit. No needles or shots are given during psychiatric interviews.

After interviews with you, and with your child, [clinician's name] will finish up the meeting by discussing "next steps" with you, and depending on the recommendations, with your child present as well. Commonly, additional input from teachers or other adults familiar with your child may be needed, so your giving consent to speak/interact with them may be discussed. In some situations, [clinician's name] may recommend certain types of treatment and discuss options, including risks and benefits of these treatments. In some cases, rating scales may be provided for you and others to describe or rate symptoms, or to measure changes as interventions are implemented.

At all times, please feel encouraged to clarify any concerns or advance any questions you may have about any part of this assessment or proposed treatment. We are eager to collaborate with you throughout this process.

Sincerely,

[Clinician's name]

APPENDIX 4.3.2

SAMPLE LETTER FOR PARENTS DESCRIBING THE ADOLESCENT PSYCHIATRIC ASSESSMENT

Dear [Parent],

We look forward to seeing [adolescent's name] on [date]. This assessment will last approximately [time allotted]. Usually [clinician's name] will meet briefly with both you and your adolescent to clarify the purpose of this assessment, and then meet for [allocated time] with your adolescent. This interview will include questions about how your teenager interacts with friends, parents, and teachers; he or she does not need to prepare for this interview. [Clinician's name] may measure your adolescent's height, weight, and pulse and blood pressure, but the adolescent will not need to change clothes or to expect to be examined like a regular medical visit. There will not be any needles or shots.

[Clinician's name] usually will then meet with the parent or guardian to review primary concerns, to obtain relevant medical and family history, and to review any sensitive information important to the assessment, but which may not have been discussed with the adolescent. Report cards, reports from school, prior clinicians, or others (daycare, courts), or educational or psychological testing reports can be very helpful, so bringing these is encouraged.

After interviews with you and with your adolescent, [clinician's name] will conclude the meeting by discussing "next steps" with the adults, and depending on the recommendations, with your teenager present as well. Commonly, additional input from teachers or other adults familiar with the adolescent may be needed, so consents to speak/interact with them may be discussed.

Confidentiality can be very important to adolescents, and issues of safety or danger are usually the only circumstances where confidentiality cannot be preserved. Often, however, sensitive subjects may warrant discussion with either the adolescent or parents/guardians alone, so our normal approach is to discuss and decide with adolescents how any sensitive information will be discussed with parents.

In some situations, following this initial evaluation, [clinician's name] may recommend certain types of treatment, and discuss options, including risks and benefits of these treatments. Rating scales may be provided for you and others to describe symptoms, or to measure changes as interventions are implemented.

At all times, please feel encouraged to clarify any concerns or advance any questions you may have about any part of this assessment or proposed treatment. We are eager to collaborate with you throughout this process.

Sincerely,

[Clinician's name]

CONCLUSION

The goal of assessment is to determine the presence of psychopathology, assess contributing factors to the presenting problem(s), and determine appropriate treatment interventions. A clinician can gain vital information through a developmentally sensitive interview with a child and parents; simultaneously, clinicians can benefit greatly from collaboration with pediatricians, schools, and

other interested adults who can offer additional insights into predisposing, precipitating, perpetuating, and even protective factors. Emphasis on rapport building, empathy for the child and parents, clear understanding of the problem(s) and function of behaviors(s), hopes and expectations of interested parties, as well as strengths and resilience factors can help facilitate accurate information gathering and successful treatment planning. Being flexible in approach and technique during the interview, genuinely listening, and taking parent and child feedback (verbal and nonverbal) into consideration can help put the family at ease and allow for more fluid sharing of information.

CHAPTER 4.4 ■ PSYCHOLOGICAL AND NEUROPSYCHOLOGICAL ASSESSMENT OF CHILDREN

KATHERINE D. TSATSANIS, LESLEY HART, AND KELLY K. POWELL

NATURE AND USE OF PSYCHOLOGICAL AND NEUROPSYCHOLOGICAL ASSESSMENT

The broad aims of a psychological and/or neuropsychological assessment are threefold: (i) to provide a more complete description and understanding of a child's behavioral, emotional, and cognitive functioning; (ii) to assist with diagnosis; and (iii) to inform strategies for intervention. This is accomplished in part through the use of psychological tests that offer an objective and standardized measure of a sample of behavior, one that allows performance to be evaluated on the basis of empirical data (1). However, it must be emphasized that psychological or neuropsychological tests and resulting test scores are but one part of the assessment process. Test selection and administration are important factors as is, above all, test interpretation. The final analysis is formed from multiple lines of converging evidence and takes into consideration the developmental and environmental context.

Psychological Assessment

Psychological tests were developed as a means to measure individual differences. Although diverse with regard to content, such measures shared a common use, which was to categorize and classify individuals based on observations of their behavior under uniform conditions (1). At the outset such measures were applied toward educational, personnel, and military classification. Differential diagnosis was also identified as a concern in the context of changes taking place in the 19th century in institutional care, and as test development was intended to aid in the educational placement of children, specifically in the study and instruction of children with intellectual disabilities. Experimental psychology was concerned with universal descriptions of human behavior, particularly in the physiology of sensory responses at this time; however, the general emphasis on the need for controlled conditions when making observations has remained at the heart of the standardization of procedures (uniform conditions) in psychological testing (1).

Early interest in educational testing led to the development of more sophisticated principles and measurement techniques that are now used to assess a wide variety of domains of functioning, including social, emotional, neuropsychological, and adaptive behavior. However, it is intellectual assessment that holds a place of

notoriety in the history of psychology. Two of the more fundamental issues that have beset intelligence testing are the definition of intelligence, and the use and interpretation of measures of intelligence. As illustrated in Table 4.4.1, theories of intelligence abound. More than this, each theorist posits multiple components or abilities as part of his account of intelligence. As such, it is worth keeping in mind that intelligence is a construct that is neither unitary nor fixed. Additionally, there is a distinction to be made between theories of intelligence and psychometric intelligence. Whereas the former provides conceptualizations of the nature of intelligence, the latter represents the measurement of general mental ability using standardized tests. The global scores yielded from these measures are usually stable and have general predictive value for educational, social, and job outcome. The instruments are limited to what they are measuring, and their interpretation is contingent on valid use, and they are of course subject to misuse.

The use and interpretation of IQ scores is an important matter and a lengthy subject. In brief, from a psychometric perspective, early approaches to psychometric intelligence focused on quantifying a general level of intelligence as represented by a single number (the IQ score) and assignment to a descriptive classification (e.g., “dull” or “very bright”). Subsequent methods have involved profile analysis or a consideration of individual areas of strength and weakness. This approach may be most powerful when integrated with theories of cognitive abilities (13). Indeed, the cross-battery assessment approach (14,15) that has emerged of late in the arena of psychological assessment emphasizes the usefulness of identifying cognitive processes versus, for example, reporting cognitive functioning in the context of a single IQ number. This represents a shift in thinking of cognitive activity in terms of a single function—intelligence—to a multifaceted entity.

Psychological Assessment Goals

The fundamental first step toward treatment planning is gaining a more complete understanding of the individual child. As noted, the psychological/neuropsychological examination is considered to be an integral part of this process. The psychologist/neuropsychologist is in a unique position to consider the influence of the child’s cognitive functioning on academic and social emotional functioning (and vice versa). One purpose for seeking an assessment is that of diagnosis and/or differential diagnosis. The referral question may focus on a diagnostic ambiguity or the question may be one of levels of functioning or the development of a specific skill. The second major purpose for an evaluation is to gain information about a child’s cognitive and academic profile and/or an augmented understanding of his/her behavioral and emotional functioning. Diagnosis is often emphasized, but what may be needed to design educational as well as treatment objectives is a more detailed assessment of the child’s strengths and weaknesses in

several areas. For example, language deficits may interfere with the child's ability to form a personal narrative; memory deficits may account for challenges in learning or treatment gains; a child's learning strengths/difficulties may inform the best modality for presenting information. Third, clinically and in research, assessment measures may be used for pre- and postcomparisons (e.g., in the case of brain trauma, in the evaluation of medication or a treatment program). Measurement through well-constructed tests further serves an important function in research toward the identification of environmental and biologic factors associated with behavioral differences (e.g., gene–brain–behavior relationships).

TABLE 4.4.1

FACTOR ANALYTIC THEORIES OF INTELLIGENCE

Thurstone's Primary Mental Abilities

Thurstone (2) identified 13 factors of which a subset was considered to represent primary mental abilities. These included spatial visualization, perceptual speed, numerical facility, verbal meaning, word fluency, memory, and inductive reasoning.

Cattell–Horn Theory of Cognitive Abilities

Cattell (3,4) proposed two distinct general factors: fluid and crystallized intelligence. Fluid intelligence refers to reasoning ability that is not dependent on prior experience, whereas crystallized intelligence represents learned or stored information. Hence, a distinction is made between those abilities needed in novel problem-solving conditions vs. rote or familiar learning strategies. Horn (5,6) modified this theory to include nine abilities: crystallized ability, fluid ability, visual and auditory processing, short-term and long-term memory, processing speed, decision speed, and quantitative knowledge.

Guilford's Structure of Intellect Model

The three dimensions of this model are operations, contents, and products. Content refers to the kind of information that is being processed (figural, symbolic, semantic, and behavioral). Guilford (7) also identifies five types of mental operations or procedures (evaluation, convergent production, divergent production, memory, and cognition), and six products (units, classes, relations, systems, transformations, implications).

Sternberg's Triarchic Theory of Intelligence

Sternberg (8) proposes a systems approach or integrative theory in which different aspects of intelligence are interrelated. The three main parts of the triarchic theory are componential, experiential, and contextual. In more recent accounts, Sternberg (9) expands his theory and examines the relationship between intelligence and the internal world, experience, and external world of the individual.

Gardner's Multiple Intelligence Theory

Gardner (10) proposes multiple types of intelligence or competencies, including linguistic, musical, logical–mathematical, spatial, bodily kinesthetic, intrapersonal, interpersonal, and naturalist. Although not easily supported, each of the intelligence is viewed as unrelated or separate in their determination.

Carroll's Three-Stratum Factor Analytic Theory of Cognitive Abilities

Carroll's (11) account of intelligence is based on an impressive meta-analysis of test-based research datasets. From this factor analysis of the data, three levels were identified: narrow (65 ability areas), broad (8 factors), and general (a single general factor, g). The second broad stratum includes fluid intelligence, crystallized intelligence, general memory and learning, broad visual perception, broad auditory perception, broad retrieval ability, broad cognitive speediness, and processing speed (reaction time/decision speed).

Das, Naglieri, and Kirby's Planning-Attention-Simultaneous-Successive Processing Model of

Intelligence (PASS)

The PASS theory (12) is based on the seminal work of A.R. Luria in neuropsychology, but is also consistent with information processing models of more recent development. Three fundamental and related functional units of the brain are considered to represent four basic psychological processes of attention and arousal, simultaneous processing (organization of information into a coherent whole), successive processing (sequential processing or processing of information in a specific order), and planning (developing the plans or strategies to arrive at a solution or complete tasks).

Neuropsychological Assessment

The traditional neuropsychological assessment is distinguished by its emphasis on producing a description and understanding of the relationship between brain and behavior. A fundamental approach to neuropsychological assessment is measurement of multiple ability domains sufficient to (i) represent the principal areas of functioning thought to be mediated by the brain and (ii) gather the information needed to address the clinical problems presented by the child (16). The assessment is typically quite comprehensive, as it is designed to sample a broad range of skills and abilities in the child. Given the emphasis on brain and behavior, it has been the longstanding practice of neuropsychologists to consider cognitive functioning as multidimensional. In describing the brain–behavior relationship, there is an implicit recognition that cognition as an operation of the brain is complex and any inferences that are made about behavior conceptualized in terms of cognition should reflect this complexity (17).

The basic neuropsychological framework for understanding dimensions of behavior reflects the functional systems of the brain. These divisions may be represented broadly as cognitive, emotional, and control processes, and as connected systems in the brain they can be thought to have reciprocal influence. The domains for assessment include (i) alertness/arousal; (ii) sensory perception; (iii) motor activity; (iv) attention; (v) memory or the encoding, storage, and retrieval of information; (vi) information processing, such as analysis and synthesis of information, problem solving, concept formation, etc.; and (vii) intentional or goal-directed activity, i.e., the organizational programs of behavior, sometimes referred to as executive functions (EFs). Alterations in motivation and emotional capacity are also evidenced in brain injury or disease and should be considered for their impact on these other systems.

A neuropsychological assessment specifically may be sought to (i) ascertain the likelihood that the child's problems in adaptation are the result of compromised brain functioning (versus, for example, the result of a psychiatric disturbance); (ii) enhance understanding of the child's psychosocial behavior by examining cognitive and control processes, such as how information is received, processed, and expressed by the child; and ultimately (iii) identify the pattern or constellation of neuropsychological assets and deficits displayed by the child toward developing

strategies for behavioral or educational intervention.

THE ASSESSMENT PROCESS

The psychological/neuropsychological assessment involves (i) clarifying the referral question, (ii) selection and administration of psychological tests, (iii) observation, (iv) interpretation, and (v) diagnostic formulation and recommendations.

Referral Question and Background History

The referral question(s) are initially identified by the parents and/or referring professional involved in the child's care. They are further refined by obtaining information from multiple sources, including interviews with key people in the child's life (parents, teachers, and other professionals), a review of past records (school reports, previous testing, and medical information), thorough history-taking, and talking with the child.

Selection and Administration of Psychological Tests

The types of assessment methods used and the breadth of the battery formed are key to test selection. Typically, a comprehensive evaluation will make use of a variety of assessment methods and assess a range of domains of functioning. One reason for sampling a range of functions lies in the fact that most psychological measures are not "pure"—that is, they do not assess one ability domain alone. It is important to discern whether, for example, on a timed task in which the child is asked to copy figures, poor performance is related to a motor, visual perceptual, attentional, and/or speed of processing issue. Difficulty on a measure of math skills may reflect limits in understanding numerical concepts, remembering math facts, understanding the *language* of mathematics (symbol use), knowing which operations to apply when sequencing (e.g., performing the correct steps in the correct order), copying errors, and/or attending to meaningful visual details (operational sign, place, columns of numbers). Test selection is guided by evaluation of the test itself and related constructs such as norm groups, reliability, and validity (see Table 4.4.2 and discussion below).

Test administration variables include the environmental setting (e.g., quiet, well-lit room, free of interruptions), establishing rapport with the child, and engaging the child in a manner so as to obtain the best possible performance. The rationale for creating optimal performance conditions is related to the purpose of the evaluation; that is, to determine if the child has the component cognitive skills or abilities necessary to function adequately (or more than adequately) at home, at school, or with others. Standardization, which refers to the uniformity of procedure in

administering and scoring a test, is also a key concept in test administration. The examiner must know and adhere to the test procedures, including presentation of directions, use of materials, response to queries, etc. In all, the assessment must be conducted effectively to obtain information regarding the level of performance that the child is capable of but also in a standardized manner to ensure comparability of the scores obtained.

TABLE 4.4.2

CRITICAL VARIABLES IN TEST SELECTION

Evidence of reliability
Evidence of validity
Representativeness of standardization group
Up-to-date norms
Ample sample (size) of normative group
Difficulty gradients (3 raw score points or more per standard deviation [SD])
Floors and ceilings (the test is sensitive enough to discriminate the lowest and highest scorers)
Clear presentation of instructions, administration, and scoring
Cost and administration time

Observation of Test Behavior

In addition to obtaining test data, the examiner makes qualitative observations of the child's presentation and performance during the test sessions. Clinical observation is an essential aspect of test interpretation. Test scores represent how a child performs on a particular test at a particular time. Qualitative observations must be integrated with the quantitative information or test scores to provide a more complete understanding of the results and conditions under which they were obtained. This includes variables such as attention, motivation, persistence, fatigue, illness, and rapport, as well as observations regarding how the child approached the tasks (e.g., use of verbal mediation, trial and error, slow but accurate style).

Interpretation of Results

Test interpretation typically involves an analysis of levels and patterns of test performance. The clinician engages in a dynamic process of hypothesis testing and information gathering, reasoning deductively and inductively from the data collected. Interpretation of test results also requires taking into consideration the behavior observed during testing and other relevant behavioral data (e.g., suspicions of a primary visual or hearing impairment) and case history information (cultural, economic, family variables).

Summary and Recommendations

Assessment conclusions and recommendations should be based on all sources of information. The comprehensive assessment is designed to identify the child's assets and deficits in a variety of domains of functioning. This approach promotes an understanding of the challenges the child faces and why, but also the strengths he/she possesses and how these can be used to help remediate areas of weakness. Inferences are derived from these data to determine the services and strategies that will facilitate the child's social, emotional, and academic functioning.

PRINCIPLES OF ASSESSMENT

The psychometric principles of assessment influence test selection, administration, and interpretation. These measurement issues are outlined below to familiarize the reader with the basic constructs and related issues.

Standardization Sampling/Developmental Norms

The raw scores obtained from tests are for practical purposes meaningless without a basis of comparison. As such, the data obtained from psychological tests are interpreted with reference to a norm group. This aspect of test development and use is fundamental as it permits that evaluation of a child's behavior need not rely on subjective interpretation alone. Rather, such norm-referenced tests offer (1) quantification of the child's level of performance with reference to his/her peer group, (2) an ipsative ("of the self") comparison or analysis of the child's performance across different measures to determine areas of personal asset and deficit, and (3) longitudinal comparison or assessment of gains/loss over time.

Norms are developed empirically on the basis of the performance of the normative sample, also sometimes referred to as the standardization sample. Standardization sampling represents the procedure used; the normative data are obtained under standard conditions with regard to consistency of item content, administration procedures, and scoring criteria. The norm group should be evaluated for representativeness, size, and relevance (18). The norm group should be a representative group of the child's peers and large enough to ensure stability of the test scores. Sattler (18) recommends at least 100 subjects for each age group in the normative sample. In most cases, test developers will draw from U.S. Census Bureau data to determine the composition of this sample based on stratification variables such as age, gender, socioeconomic level, race, geographic region, etc. Many instruments will also offer normative data obtained from special populations to permit comparisons of the child to other children with the same disorder (a peer group as well).

Reliability

The reliability of a test refers to the consistency of measurement; as such, it also speaks to the degree to which test scores are free from random fluctuations of measurement (19). The example of a scale used to measure weight vividly illustrates the importance of the stability of test scores as concerns accuracy or dependability of measurement. Let us say that on one day when you step on the scale it shows a weight of 150 pounds, 100 pounds on the next day, and then 175 pounds the following day. The scale could not be considered a meaningful or accurate measure of your weight. The same could be said for a psychological test that is not reliable. Test results are not interpretable if the test is not reliable, making reliability a fundamental factor in test selection and interpretation.

TABLE 4.4.3

OVERVIEW OF TYPES OF RELIABILITY

Types of Reliability	Description
Test–retest reliability	A measure of temporal stability. The reliability coefficient is expressed as r_{tt} and is the correlation between scores obtained by the same persons taking the same test on two different occasions.
Alternate-form reliability	Consistency of test scores when alternate forms of a test are given to the same person. The tests may be given at different times or on the same occasion. As such, this method may be used to minimize practice effects and also to examine whether two different forms (items and item composition) of the test give the same result.
Split-half reliability	A measure of internal consistency or consistency of the content of the test. This type of reliability is measured from a single administration of a single test form, splitting the test in half (e.g., odd and even items of the test) and comparing the two half-scores, usually by means of the Spearman-Brown formula.
Inter-item reliability	Another measure of internal consistency using a single test form and a single administration. In this case, however, reliability is measured based on performance on *each* item relative to the other items of the test and thus gives some indication of the homogeneity of the measure. The usual formula used is Kuder Richardson (when items are scored 0 or 1) or Cronbach's alpha coefficient (for items not scored as right or wrong).
Interrater reliability	Apart from temporal, content, and examinee variables, variance in test scores can arise from examiner factors, such as differences in scoring. Interrater reliability provides a measure of consistency of scores obtained when the same test is scored by two different examiners. This is an especially critical variable when evaluating test forms that leave judgment open to the scorer.

There are different types of reliability, each of which reflects a different aspect of how a test score is reproducible (Table 4.4.3). The reliability coefficient, symbolized by the letter *r* with two identical subscripts, is used to express the degree of consistency of test scores. It is a particular kind of correlation coefficient with a range of .00 (indicating no association or consistency between scores) to 1.00 (perfect reliability). No assessment measure is 100% reliable, and as such, some error of measurement is to be expected. The reliability coefficient can be used to

determine the degree of error variance or random or unsystematic variation in the measurement instrument (1). The error variance of a test is calculated by subtracting the reliability coefficient from 1.00, where 1.00 indicates perfect reliability. Thus, a reliability coefficient of .80 indicates 80% reliability and 20% error variance. Typically, a minimum acceptable level of reliability is .80 (18).

The reliability coefficient is an important number as a measure of consistency, but also as a source of the amount of reliable variance associated with the test. As such, it is used in the calculation of the standard error of measurement (SEM) of a test score and in turn the confidence interval. Scores for a psychological test (e.g., an IQ score) are often reported as falling within a specific range of scores, or within a confidence interval. The psychometric properties of a test are such that although they may aim to quantify level of functioning in a real way, the obtained test score is actually composed of a true score (hypothetical) and an error score (1). The confidence interval represents the range of scores surrounding the obtained score within which the true score is likely to lie. For example, if a child obtains an IQ score of 90, we can state at the 95% confidence level (the usual reported level) that her IQ score on any single administration of the test will lie between 84 and 96. That is, 95 times out of 100, her IQ score will fall within this band of values. The confidence interval is determined by the SEM for the instrument, which in turn is computed from the reliability coefficient.

The major point to underscore here is that the obtained test score is not precise or definitive, as each test inherently contains measurement error that should be taken into consideration when decisions are being made based on a single score (e.g., IQ score for qualification of services). The second and related point is that measurement error must be accounted for when reported scores are compared over time or across instruments. The difference between two test scores may be due to chance factors or the error variance associated with each test. Correspondingly, the reliability coefficient for each test is taken into consideration in the calculation of discrepancy scores.

TABLE 4.4.4

OVERVIEW OF TYPES OF VALIDITY

Types of Validity	Description
Construct validity	Examines the extent to which a test measures what it purports to measure, such as a psychological construct or trait. Two constituents of construct validity are *convergent* (measures of related constructs should correlate) and *divergent* (measures of unrelated constructs should not correlate) validity.
Content validity	Refers to the degree to which a test covers the behavior or skill or subject matter being measured. A discussion of the content validity of a test should help to answer whether the test offers representative coverage of the domain assessed, and whether there is influence from other variables.
Face validity	As the name suggests, face validity refers to whether on the surface of things the test

	appears to be appropriate for its intended use.
Concurrent validity	A form of criterion-related validation in which the current measure is compared to a criterion or outcome to which it is related (e.g., ratings or other test scores).
Predictive validity	Another form of criterion-related validation that examines the degree to which the measure predicts some other criterion in the future (e.g., IQ and later academic success).
Treatment validity	Refers to the clinical utility of an instrument as it relates to the impact of the test results on the examinee's behavior.

Validity

Test validity is a term used to represent the meaning or relevance of a test, specifically, whether it measures what it is purported to measure (1). It is a fundamental psychometric concept that can be approached in several ways, as detailed in Table 4.4.4. The validity of a test is relevant when assessing what is being measured and how completely, as well as how to use a test appropriately. Validity coefficients are a type of correlation coefficient and accordingly are impacted by the range of attributes being measured (the narrower the range, the lower the value of the validity coefficient). Examinee variables also can impact validity; if an examinee presents with severe test-taking anxiety, extreme fatigue or illness, a hearing or vision impairment (and, for example, forgets to wear her glasses), or fails to understand the instructions, these factors are likely to render the test scores invalid, as the test is no longer measuring the characteristic it is intended to measure. As such, psychological reports include a section on observations of test behavior and a description of any presenting factors that are a threat to validity. Extrinsic or environmental factors such as socioeconomic status, access to quality teaching or textbooks, or cultural experiences can similarly impact validity and are addressed in the interpretation of test scores.

INTERPRETATION OF TEST SCORES

Derived Scores

A basic feature of interpretation of test scores is the comparison of scores to some standard or norm. As mentioned above, raw test scores, whether the number of points earned, items successfully completed, or symptoms endorsed, are meaningless on their own. Rather, the raw test score is evaluated relative to the test performance of the standardization sample. The question that is answered in this process is where this particular child's score falls relative to the distribution of scores produced by the standardization sample, where the mean represents the average and the standard deviation (SD) represents the variability. There are a variety of derived scores or ways in which this comparison can be reported.

Standard Scores

Standard scores are the most typical and often the most suitable kind of score to report. Standard scores are particularly useful for making comparisons across tests, as the mean and SD are set and there are equal units along the scale (19). For all standard scores, a score falling 1 SD below the mean (below the average range) or a score falling 2 SD above the mean (well above average) occupies the same position relative to the group apart from the instrument used. Comparability of scores in this manner is achieved through a transformation of the raw data. The usual types of reported scores are standard scores, scaled scores, and T-scores (Table 4.4.5). The typical standard score has a mean set at 100 and an SD of 15. Most major cognitive and achievement assessment batteries report global scores in this format. Individual subtest scores, however, may be represented as scaled scores with a mean of 10 and an SD of 3. Some tests and many behavior checklists yield T-scores, which have a mean of 50 and an SD of 10.

Percentile Scores

Percentile scores are a popular means for reporting test performance as they are easy to understand; a percentile rank is a way of positioning the child's performance relative to the norm group in familiar terms (18). For example, a percentile rank of 84 indicates that the child scored as well as or better than 84% of the norm group. There are some caveats. Naïve consumers of these test scores may confuse percentile ranks with percent of items passed (such as an 84% on a test). A major concern also with regard to percentile ranks (vs. standard scores) is that the units are unequal. The numbers can be deceptive and may overemphasize or underemphasize differences between standard scores. For example, note that scores between the 25th and 75th percentile are all within the average range.

TABLE 4.4.5

Z-SCORES AND DERIVED SCORE EQUIVALENTS

Z-Score	Standard Score	T-Score	Scaled Score	Percentile Rank
−3	55	20	1	1
−2	70	30	4	2
−1	85	40	7	16
0	100	50	10	50
+1	115	60	13	84
+2	130	70	16	98
+3	145	80	19	>99

Age and Grade Equivalent Scores

Test scores in some cases are also reported in terms of age and grade equivalents.

An age equivalent score is determined based on the performance of each age group in the norm sample. If the average raw score of the 8 year olds in the sample is 14, then a raw score of 14 yields an age equivalent of 8 years. Age equivalent scores thus describe the raw score obtained and do not necessarily correspond to the child's level of functioning, nor do they represent equal units.

Grade equivalents are similar in that grade norms are computed from the mean raw score obtained by children in each grade in the standardization sample. Again, if the average raw score on a reading test for single words corresponds to 25 for fourth graders, then a raw score of 25 corresponds to a grade equivalent of 4. Grade units are unequal and do not represent the variability between subject areas at different levels. It is also important to recognize that when a fourth-grade child obtains a grade equivalent score of 6.5 on an arithmetic test, it does not necessarily indicate that the child is capable of grade 6 arithmetical processes or should be placed in the seventh-grade curriculum (1). Rather, the child's total raw score may reflect superior performance on fourth-grade arithmetic. The point is that psychological tests are typically constructed to provide a range of scores. If we consider the standardization sample of children in the fourth grade, there will be a distribution of scores for this group of children; an average raw score for this group will represent the average score on the test at the fourth-grade level. The children who perform well above average within this distribution will produce a well-above average score on the test for their comparison group and may in turn share a total raw score with the average sixth grader. Additionally, the same raw score yielding the same age or grade equivalent could be obtained in a very different way relative to the individual items of the test and thus have a different meaning. Although appealing, age and grade equivalent scores are easily subject to misinterpretation; they do not necessarily reflect a particular level of knowledge but are rather another means of indicating where a child falls relative to a particular kind of reference group (19). On the other hand, the advantage of reporting scores in this format is that they are easily understandable and place performance within a familiar developmental context. In this case, correct interpretation is paramount.

Descriptive Levels

In addition to a quantitative representation of performance, classification of ability levels is applied to standard scores, based on whether the score corresponds to the average performance of the normative group or, for example, the upper or lower extreme end of the distribution. These descriptions of performance are widely used to represent how far a child's score deviates above or below the mean. The qualitative descriptors provided vary from instrument to instrument. Two examples are detailed in Table 4.4.6. In the event that a child's file contains several different reports, one should keep in mind that derived scores can be converted to a uniform

metric for comparison. Knowing the child's test score, the mean and SD of the test, and assuming that the scores on the test fit to a normal distribution (which would be true of most major assessment instruments), then it is easy to determine where the child's scores fall relative to the mean. This would be achieved by taking the child's test score, subtracting the mean, and dividing by the SD. Thus, if a child obtained an IQ score of 115 on a test that has a mean of 100 and SD of 15, his or her score would be 1 SD above the mean. Similarly, if the same child obtained a T-score of 60 on a different measure (with a mean of 50 and SD of 10), his or her score would also be 1 SD above the mean. If percentile scores are reported on a given test, these too can represent the child's position relative to the standardization sample (see Table 4.4.5). A special note about IQ scores: The traditional means of obtaining an IQ score (or intelligence *quotient*) was to take the ratio of mental age (MA) divided by chronologic age (CA) and multiply by 100. The problem with this procedure is that ratio IQ scores at different ages are not comparable and thus not psychometrically sound in practice. Although the term IQ has been retained, current measures of IQ do not derive scores based on the above formula; rather, these so-called deviation IQs are a type of standard score and as described above fit to a distribution with a mean of 100 and an SD of 15. However, knowledge of the ratio IQ is handy when there is limited information and a need to make a *rough* approximation of the child's ability level.

TABLE 4.4.6

CLASSIFICATION OF ABILITY LEVELS

Standard Score	Percentile Rank	Descriptive Classification[a]
69 and below	<2	Extremely low
70–79	2–8	Very low
80–89	9–23	Low average
90–109	25–73	Average
110–119	75–90	High average
120–129	91–97	Very high
130 and above	98–99.99	Extremely high

Standard Score	Descriptive Classification (10-Point Scale)[b]	Standard Score	Descriptive Classification (15-Point Scale)[b]
69 and below	Very low	40–54	Very low
70–79	Low	55–69	Low
80–89	Below average	70–84	Below average
90–109	Average	85–115	Average
110–119	Above average	116–130	Above average
120–129	High	131–145	High
130 and	Very high	146–160	Very high

Significant Difference

Derived scores and classification of ability levels provide a means to compare a child's performance relative to his or her peers as defined by the norm group. However, test interpretation also involves a comparison of the child's different ability levels across domains of functioning and in some cases across time. For example, we may want to know whether Sam is more able on verbal versus visual spatial tasks, whether Alice's reading skills are consistent with expectations given her overall IQ, or whether ratings of Justin's behavior at home and school are significantly different. There are two considerations to keep in mind when comparing whether two scores are different or not: (a) statistical significance and (b) unusualness or abnormality of difference. The first, statistical significance, answers whether the results differ from what would be expected based on chance alone (18). The usual *p*-value for this calculation is .05, meaning that, if the difference between two scores is significant (not due to chance factors), we accept a 5 out of 100 chances of being wrong. Test publishers will report domain and subtest score differences in their manuals or computerized printouts. When making comparisons between two different tests, either of the following two calculations can be made, which take into account the error variance of each test:

$$SE_{diff} = \sqrt{}(SEM_1)^2 + (SEM_2)^2$$

$$SE_{diff} = SD\ \sqrt{}2 - r_{11} - r_{22}$$

The standard error of the difference (SE_{diff}) is then multiplied by 1.96 to determine how large a score difference could be obtained by chance at the .05 level (1).

In addition to answering whether two scores are significantly different in statistical terms, the second part of interpretation lies in determining whether the difference is clinically significant. One way to address this particular question is to examine base rate frequency; that is, to ask how unusual it is to find this difference in scores. Test publishers of cognitive and achievement test batteries will typically provide this information in supplementary tables. A difference of scores that is found in only 5% of the norm sample can be considered unusual and highly unusual when present in only 1% of the sample.

Sometimes standard scores in a domain of functioning may decline over time. This finding does not necessarily represent a deterioration or regression, but rather, may reflect a failure to make age-appropriate gains (rate of gain slower than rate of

change in chronologic age). If standard scores on the *same* test are found to be significantly different across time, it would be important to look at the raw scores and pattern of scores obtained on each test before assuming there has been a loss of skill. Additionally, of course, it will be important to consider other variables that might have affected the test performance (such as fatigue, illness, compliance). Table 4.4.7 lists several other factors to consider when test scores for the same child on (ostensibly) the same kind of test differ (the child scores in the intellectually disabled range on one cognitive test but not another). These factors are important to consider, particularly in the interpretation of IQ scores, as they impact diagnosis and the procurement of services.

TABLE 4.4.7

SOME REASONS WHY TEST SCORES MAY DIFFER

Norms	A difference in the age of the norms could impact test scores. The Flynn effect refers to a finding by J.R. Flynn (22) that there is a continued rise in IQ test performance. The average rate of rise seems to be around three IQ points per decade. The composition of the normative sample used to develop the test scores is different and may represent a less or more able group.
Test Units	The scores are reported in different units of measurement. For example, a score of 115 on one test and a score of 60 on another may in fact represent the same level of performance if in the case of the former the mean is 100 with an SD of 15 and in the case of the latter the mean is 50 with an SD of 10. Alternatively, two tests could both have a mean of 100 but different SDs.
Floor and Ceiling Effects	Floor effects occur when the test lacks enough easy items to discriminate between low scorers, and ceiling effects refer to when the measure lacks enough hard items to adequately assess upper levels of ability. A raw score of 0 on one test may produce an IQ score of 40 but an IQ of 70 on another test as a result of differences in the lower limits of the test items. If the referral includes a question of MR, test selection is paramount to ensure adequate range at the lower levels to make this discrimination.
Correlations Between Tests	Two tests may yield score differences because the tests are not correlated or only moderately related.
Reliability	Test scores for children 5 yrs of age and under are typically less reliable than those obtained in school-age children. Test length can also affect reliability. To determine how large a difference is needed for statistical significance (to be confident that the discrepancy between scores is not due to chance factors alone), a calculation is made that takes into account the reliability of each test.
Item Content Differences	Tests intended to measure the same domain may diverge in content and response despite sharing a similar name. For example, IQ measures may differ in terms of the level of language, memory, and/or speed of processing demands that factor into the overall score. A reading comprehension test may involve reading a sentence or a passage, aloud or silently. Additionally, the response required may be dissimilar between tests, ranging from filling in a missing word, enacting what is read, or responding to oral questions about what was read.
Practice Effects	Scores may improve because of familiarity with the test or test items or prior exposure. Practice effects appear to be most pronounced on nonverbal vs. verbal tasks, perhaps because of their novelty. Most tests should not be re-administered until after a period of time has passed (typically, 1 yr) in order to minimize such effects.

Other Factors	Differences related to variables such as fatigue, illness, medication, motivation. Actual gain, loss, or discrepancy in skill level can be noted.

Levels of Analysis

Interpretation involves the analysis and synthesis of all of the data obtained as part of the assessment. To assure ecologically valid conclusions regarding adaptive behavior, it is necessary to sample a wide variety of abilities and skills that interact for successful accomplishment (16). Test performance is examined for statistically significant discrepancies between observed and expected levels. Expected levels of performance may be based on earlier known levels of functioning, age norms, and/or other abilities. It is also generally expected that test scores will converge around the same level, and when functions are not proportionate, one should consider factors such as uneven brain development or brain disturbance, socialization, educational experience, emotional disturbance, physical illness/fatigue, economics, or primary sensory impairments to account for discontinuities in the child's profile (17). Base rates and contextual factors must be taken into account for those discrepancies that are commonly found in the normal population or those measures that are differentially sensitive to cultural, economic, and educational background (e.g., vocabulary level). The test results are further examined for particular patterns of performance. Comparisons may be made along the following lines as examples: domain of functioning (language, visual spatial, memory, problem-solving skills), modality (visual, auditory, tactile), level of task difficulty (simple or complex), speed of processing (speeded versus no time limit), closed or open response structure (forced choice versus generative, recognition versus recall), laterality (right vs. left performances), and so on. Strengths and weaknesses in the child's information processing are thus examined according to how the information is represented and processed, as well as the nature of the response that is required.

DOMAINS OF ASSESSMENT

The domains of functioning assessed and the methods used in psychological/neuropsychological testing are far reaching in their scope, with an overview presented in this section. Individual tests are selected relative to the clinical or research need and developmental capacities of the child or adolescent initially based on an understanding of the child developed from prior assessment and clinical history, and updated with additional tests and subtests to evaluate diagnostic hypotheses based on performance during assessment. Many commonly used assessment instruments organized according to the functional domain assessed are presented in Tables 4.4.8 and 4.4.9. Computer-assisted assessment and scoring is also available for many of these instruments. For more detailed information, key

resources on psychological assessment as well as test selection and acquisition are identified in Table 4.4.10.

Psychological Assessment

General Ability and Intelligence

Broad measures of cognitive ability and intelligence provide an estimate of a child's general ability level at a particular point in time in relation to the given age norms (1). Although most cognitive or intelligence tests yield a single IQ or ability score, this should not be interpreted to suggest that intelligence is a single unitary construct. Rather, such measures are typically composed of a variety of subtests measuring a range of functions. Careful interpretation involves an analysis of domain and subtest scores for areas of normative and relative strength and weakness. It is also worth noting that such tests are developed based on different theories of intelligence. Thus, in spite of assessing a shared construct, intelligence tests may differ greatly in terms of content, including emphasis on verbal versus visual information, extent to which speed of processing is emphasized, the type of response format, and so on. In general, tests of cognitive ability and intelligence assess the extent to which a child has acquired information and is able to think abstractly. IQ scores are generally stable in children 5 years of age and older and are predictive of academic abilities in school-aged children. IQ and cognitive assessments may provide useful information with regard to how the child takes in, processes, and responds to information, useful toward treatment planning and provision of differentiated instruction.

Achievement

Achievement tests measure educationally relevant skills or acquired knowledge in subject areas such as reading, spelling, mathematics, written expression, science, social studies, and humanities. Such tests provide a means of identifying strengths or weaknesses in the acquisition of basic academic skills and knowledge in core subject areas. In the past, learning disability (LD) service eligibility had been determined on the basis of IQ-achievement discrepancy scores. There were a host of problems with this approach, both theoretically and practically, including for example that the magnitude of the difference (typically greater than 1 SD) could vary between school districts. The Individuals with Disabilities Education Act (IDEA), revised in 2004, does not allow the use of a discrepancy definition of LD, but instead recommends the use of a procedure for assessing students' response to scientific, research-based intervention. This Response to Intervention (RTI) approach uses a tiered approach in which students receive mainstream education at Tier 1, additional instruction in small groups at Tiers 2 and 3, and only after they have failed to meet benchmarks with this additional instruction, evaluates for special educational services and LD.

Thus, children receive services before they are allowed to experience school failure to a point at which they are significantly behind their peers, a requirement of the discrepancy definition of LD. See Fletcher et al. (109) and Fuchs and Vaughn (110) for more information. IDEA also recognizes the importance of examining various cognitive processes and their impact on school learning (111). For example, phonologic awareness, familiarity with words, and ability to retrieve words rapidly are relevant components of reading and spelling competence, and these and other cognitive abilities such as nonverbal reasoning have been found to predict reading ability as much as 5 years later (112). Deficits in working memory are likely to impact math learning, and planning and organization problems can affect written expression. Of note, achievement tests differ widely in content, presentation, and response format. Reading comprehension, for example, may be assessed using written words, sentences, or passages, with responses to oral questions or by filling in the blank. Decoding may be measured using real words, in which vocabulary and sight word recognition can drive scores, or using pseudowords, a more "pure" measure of decoding. Math questions may be presented orally or as a written calculation, with or without visual support, and timed or untimed. Therefore, in interpreting achievement scores, it is also important to understand how the subject matter was assessed.

Behavioral, Social, and Emotional

As a complement to direct behavioral observation and clinical interviewing, behavior rating scales and personality inventories offer a psychometric approach to assessing social emotional problems in children and adolescents (104,113,114). General-purpose rating scales provide information about multiple areas of psychopathology as well as attitudes and interpersonal relationships whereas single domain syndrome measures typically assess specific areas such as depression or anxiety according to DSM criteria. Personality tests or inventories are intended to assess relatively stable characteristics of the individual, but in children usually cover a range of psychological and adjustment problems. Social competence measures focus on the assessment of social skills as well as peer relationships; most behavioral scales and personality inventories include these domains but not to the same extent. Behavioral summaries are based on checklists that use dichotomous ratings and an additive scale; the symptom is rated as present or absent and the number of checked items is summed. Rating scales, on the other hand, permit an indication as to whether a symptom is present or not and also the degree to which it is present in terms of frequency (never, sometimes, usually).

Handbook of Psychological Assessment (107)
Practice of Child-Clinical Neuropsychology: An Introduction (16)
Neuropsychological Assessment (5th edition) (17)
The Neuropsychological Evaluation of the Child (108)

Through the assessment of behavioral, social, and emotional functioning, information is obtained in a systematic and standardized format, producing quantified data, relative to normative developmental reference groups. In addition, rating scales make use of the judgments and observations of others who are familiar with the child, including the child him/herself, parents, or teachers. In some instances, it is possible (and useful) to compare results between reporters and settings. As with other types of measures, scale names may be similar across behavioral instruments, but item content may differ; also, scales of different names may share content (e.g., when hyperactive behaviors are subsumed under the conduct domain) (103,114). Although objective in the sense that information is collected under standard conditions, rating scales are subject to respondent variables. Most behavioral measures include scales to assess the response style of the informant, such as whether the individual is reporting in a manner to create a favorable impression ("faking good"), an unfavorable impression ("faking bad"), a more/less socially acceptable picture, as well as to evaluate consistency of response. It is important to interpret these scales first in order to

determine whether the results as a whole are valid.

Projective techniques are another method for accessing the “inner life” of the child or adolescent. This assessment method may in fact be particularly useful for children and adolescents. Tasks such as drawing, completing sentences, and providing narratives to pictures may be more engaging and less confrontational than direct questioning. (See Frick et al. (104) for a discussion.) The projective techniques are based upon the premise that responses to and interpretations of ambiguous stimuli provide insight into the examinee’s unconscious mental processes, such as needs, motives, and conflicts. Most projective tasks have been in longstanding use and continue to be widely employed; several have an extensive research literature (such as the Rorschach Inkblot Test and Thematic Apperception Test). Although an understanding of projective techniques is typically embedded in psychodynamic theory, these measures can also be viewed as an additional means of capturing how the child processes and organizes novel, ambiguous, or unstructured information.

Adaptive Behavior

Adaptive behavior scales measure domains related to personal independence and social competence. These are the day-to-day activities necessary to take care of oneself and get along with others, as defined by age and cultural standards. The usual domains assessed include independent living skills (eating, toileting, simple household chores), functional communication and academic skills, fine and gross motor skills, as well as social behavior such as relations with others, participation in leisure activity, and awareness of community rules. An assessment of adaptive behavior enhances the clinical picture of a child or adolescent by providing information about what the individual *actually* does, as opposed to what he or she is capable of doing in the home, school, or community. It is especially valuable when working with children with developmental disabilities toward treatment planning and toward intellectual disability classification. As with other measures, interpretation of the results requires a consideration of the variables that are likely to impact performance, including motivation, family expectations, cultural values, and level of cognitive functioning.

Diagnostic Interviews

The unstructured clinical interview is commonly used in psychology, as in psychiatry. However, several instruments are available for use that offer a more structured and uniform approach to the diagnostic interview, which is of particular relevance in research but is becoming increasingly used in the clinical setting (115). These interviews are tied to DSM criteria and provide a set of questions and explicit guidelines for how responses are to be scored. They offer the following advantages

when compared to behavior scales: They provide information about symptom duration and onset, intensity and level of impairment, and are tied to diagnostic criteria. The explicit interview format may also be helpful for the interviewer in training. Disadvantages include the use of these instruments requires more time (60 to 90 minutes), they are not norm-referenced, and they are subject to the biases of the reporter, which are not captured in any systematic way (104). There are four other factors to keep in mind when evaluating diagnostic interviews relative to one's research or clinical needs. First, there are usually multiple versions of the same instrument (as they are being constantly updated as DSM criteria change). Second, although the interviews are structured, they vary in their degree of explicit instruction (e.g., the Schedule for Affective Disorders and Schizophrenia for School-aged Children (57) provides questions to guide the examiner, whereas the Diagnostic Interview Schedule for Children (56) requires the questions to be read as written). Third, most interview responses are scored in a dichotomous fashion (present or absent), although some instruments permit a rating of severity for each symptom, allowing for assessment of subclinical presentations. The last point to be made is that the time frame used to assess symptomatology differs among instruments, for example, in terms of how "present episode" is defined, and also whether lifetime diagnosis information is collected. (See Frick et al. (104) for a further discussion.)

Neuropsychological Assessment

A comprehensive neuropsychological assessment will include measures in one or more of the domains above. The basic test battery will also evaluate cognitive behavior in depth by including measures in each of the following domains and then selecting tests to emphasize one area or another according to initial results of the child's particular pattern of assets and deficits.

Sensory Perception

Measures of tactile, visual, and auditory perception are fundamental to the neuropsychological assessment battery. At a basic level, the individual will be evaluated for evidence of sensory imperception and suppression in each sensory domain, and on each side of the body. Higher-level perceptual abilities also are evaluated in each domain. A comparison of performance on the two sides of the body is significant for evidence of lateral or bilateral brain impairment. Each sensory system is also subserved by different regions of the brain and thus yields initial information about areas that are likely to be maximally involved (16). This aspect of the assessment is also relevant to particular types of brain impairment, such as the agnosia. From a developmental perspective, information about the child's sensory and perceptual processes is essential to understanding how the child takes in and

assembles information in each of these domains and evaluating the impact on more complex or higher-order information processing.

Motor Skills

Motor ability is assessed for basic skills such as force, speed, steadiness, and dexterity; it may also be evaluated in the context of more complex skills such as visual motor coordination, visual motor integration, and constructional abilities. If a deficit in one of these multisystem tasks is obtained, then an analysis of each of the individual component processes is important. Motor function is examined both for overall level as well as laterality. It is relevant to the performance of activities of daily living, play, leisure involvement, classroom tasks, drawing, and handwriting. Assessment of motor and visual motor function is relevant to the question of apraxia.

Attention

Attention is a core capacity that is central to the processes of information reduction, response selection, and preparation for eventual action. The widespread use of the phrase “pay attention,” illustrates that attentional resources come at some cost and require effort (we have to “concentrate hard”). Further, there is an implicit notion that attention is selective (we pay attention to one aspect of a complex environment to the exclusion of another). New information arrives in the form of a continuous flow of both internal and external stimuli. Children develop an increasing capacity to override the impulse to attend to what is most striking or novel or desired in order to anticipate, direct, or guide attention, based on prior knowledge and internal goals. Components of attention are distinguished in terms of modality (e.g., tactile, auditory, visual) and process (e.g., focusing or sustaining attention and shifting or dividing attention) assessed. Intact attention is relevant for focused behavior as well as mental tracking (such as following a sequence of ideas or steps in one’s head) (17).

Memory

It is important to understand the role of memory, as very few aspects of higher cognitive function and learning could operate successfully without some memory contribution. Memory is often treated as a unitary construct but should be recognized as comprising multiple interrelated systems. Performance may be modality (verbal or visual), task (recall versus recognition), or system (immediate vs. long term; semantic vs. episodic; implicit vs. explicit) specific. Organization has a role in memory, as do other executive control processes. Working memory tasks require the ability simultaneously to attend to, recall, and act upon information held in an online state. This aspect of memory function is often considered in the domain of EF and is fundamental to most aspects of problem solving.

Language

Language is typically assessed for the intactness of the child's ability to discriminate and produce speech sounds, repeat words and phrases, retrieve words rapidly, appreciate word meanings, make verbal associations, and express him/herself, as well as comprehend more complex utterances (16), understand and use nonliteral language, and understand and use language in social contexts. The significance of assessing language abilities is understandable, with regard to the functional lateralization of this system (e.g., left cerebral dominance), evaluation of the aphasias, as well as the importance of language development with regard to reading, spelling, and written expression, concept formation, and the regulation of behavior.

Problem Solving, Concept Formation, and Reasoning

Measures of problem-solving ability, concept formation, and reasoning have in common an emphasis on abstract reasoning ability; the task demands are typically complex and require higher-order problem-solving strategies. The stimuli may be verbal, visual, or tactile in nature, although the child may restructure the task such that a visual task is verbally mediated or a verbal reasoning measure is guided by visual imagery (16). Conceptual and reasoning tasks are likely to represent the integrity of brain functioning, given the need for recruitment of multiple systems in the performance of such tasks. Such tasks provide insights into how the examinee thinks, for example, revealing concreteness and/or mental inflexibility to form concepts and logic relationships.

Executive Functions

EF is a term generally used to capture several higher-order cognitive functions. It refers to the ability to maintain an appropriate problem solving set to guide future goal-directed behavior, and is composed of a set of abilities including (1) inhibition, (2) set shifting, (3) planning, (4) working memory, and (5) self-monitoring. Most cognitive or intelligence test batteries do not comprehensively assess this domain. Adequate assessment of these areas is relevant to evaluating the child's ability to formulate plans of action, test hypotheses, benefit from feedback, and work toward an end goal. The child who presents with problem solving (as above) and/or EF deficits is likely to require a greater deal of structure and contingent feedback in his or her treatment or educational program.

COGNITIVE AND LEARNING CHALLENGES IN PSYCHIATRIC AND NEURODEVELOPMENTAL DISORDERS

There is consistent evidence that psychiatric and neurodevelopmental disorders of

childhood are associated with cognitive and learning challenges, although the pattern is neither uniform (there is considerable heterogeneity within disorders versus a single core deficit) nor diagnostic (specificity is often lacking and process deficits are being identified that are shared across disorders). (See Coghill (116) for a discussion.) The constellation of behavioral deficits that encompasses attention-deficit hyperactivity disorder (ADHD) is typically identified relative to day-to-day behaviors in real-world settings. It would be reasonable to consider that performance-based measures of EF deficits would also be consistently associated with ADHD; however, the evidence suggests that the degree and nature of involvement varies in children with ADHD and the presence of EF deficits does not necessarily lead to a higher level of ADHD symptoms but rather potentially represents a notable subtype (e.g., 117,118). Different diagnostic groups may be distinguished based on profiles of everyday EF problems; for example, children with Tourette syndrome (TS) showed elevations in the domain of emotional control relative to elevated concerns for inhibitory control for children with ADHD-C, planning/organization for children with ADHD-I, and cognitive flexibility for children with ASD (119). Indeed, conceptual flexibility versus perceptual or attentional flexibility (or simple inhibitory control) appears to be the predominant deficit in higher-functioning individuals with autism (120–123). Sustained attention for simple repetitive visual information is generally intact in individuals with autism compared to developmentally matched controls, as measured by continuous performance tasks (124–128). TS is associated with problems with attention, fine motor coordination, and visual motor integration, where fine motor skill deficits may be a predictor of future tic severity and global psychosocial function in children with TS (129). In addition, although the disorder is defined by the presence of tics, it is the co-occurring disorders such as behavioral disinhibition, hypersensitivity to sensory stimuli, problems with visual motor integration, ADHD, obsessive–compulsive disorder, depression, and anxiety that may be especially impairing and thus important to assess (130). Anxiety and depression may impact attention, memory, and learning. Bipolar disorder has been linked to impairments in sustained attention, working memory, and processing speed after controlling for ADHD (131). Neuropsychological studies of childhood onset schizophrenia have revealed deficits in attentional capacities and the processing of information (132–136). Premorbid neuropsychological deficits are also reported in a large proportion of children who later develop schizophrenia, and less so in bipolar disorder, suggesting neurodevelopment underlying cognition in children prior to the onset of schizophrenia may be especially impaired (137).

Several disorders clearly necessitate a psychological or neuropsychological evaluation, such as suspicion of an LD or intellectual disability. One specific type of LD, nonverbal learning disability (NLD), is defined by a profile of neuropsychological strengths and weaknesses. The NLD syndrome is so named

because the clinical presentation is thought to arise from deficits that are primarily nonverbal in nature (138). These primary deficiencies, which include visual, tactile, and motor functioning, also impact apprehension and use of nonverbal aspects of communication, such as facial expressions, gestures, and general body language. Academically, these children show better reading and spelling skills relative to arithmetic. At present, there is no formal provision for NLD in the DSM-5, although rules for classification have been developed (139,140). For the purposes of obtaining services, the needs of these children may be partially captured by diagnostic labels such as specific learning disorder with impairment in mathematics or written expression.

SUMMARY: INTEGRATED APPROACH

The psychological and neuropsychological assessment represents a systematic process for arriving at a more complete understanding of the child. The determinants of human behavior are many and varied; accordingly, when presented with problem behaviors, thought must be given to factors both intrinsic and extrinsic to the child. Intrinsic factors include (a) cognition and learning, which can be thought of as the information processing aspect of behavior; (b) emotional status, including feelings, motivation, regulation; and (c) EFs or execution of purposeful behavior (17). An overly simplistic approach is eschewed in favor of considering the relative contributions of each of the domains, the processes within them, and most interestingly, their interaction (e.g., the impact of a child's cognitive style on his/her affect, how a child's emotional state impacts information processing). In the final analysis, this information is integrated with extrinsic factors, including past experiences, current environmental demands, and the availability of resources toward guiding future treatment planning.

CHAPTER 4.5 ■ ASSESSING COMMUNICATION

RHEA PAUL AND MEGAN C. LYONS

This chapter provides a brief outline of the process involved in assessing how children use speech and language for communication. We describe clinical assessment as a process that involves screening, evaluation—the process of establishing the degree of disability and diagnosis that best fits based on evidence from the child's history and performance and/or to establish continuing eligibility for services—and assessment, the ongoing process of gathering information to monitor the child's progress, strengths and needs and to make educational decisions (1). Evaluation, ideally, is conducted by a team of professionals from multiple disciplines who contribute their expertise in identifying the child's disorder and needs. For very young children (birth to 3 years), the evaluation team may include family members, a service coordinator, and persons conducting the evaluations and typically takes place in natural environments (e.g., home or daycare setting). For school-age children, The Individuals with Disabilities Education Act (1) regulations identify members of the team as: parents; regular education teacher; special education teacher; representative of the public agency, and at the discretion of the parent or agency, other individuals who have expertise regarding the child. Older children may also be included in the team. A speech-language pathologist (SLP) is the member of the team who specializes in the assessment and treatment of disorders of communication, including speech, language, and hearing. Qualified SLPs are certified by the American Speech-Language-Hearing Association (ASHA), and usually licensed by the state, as well.

Assessment of communication typically includes the evaluation of:

- Articulation: the pronunciation of the sounds of speech. Errors of articulation can be confined to the distorted production of a few sounds, such as a lisp. Alternatively, a speaker may substitute a range of sounds for others (saying /dot/ for *goat* or /to/ for *sew*), or may omit sounds in words ('pay' for *play*; 'so' for *soap*). Some articulation errors may make speech sound childish or immature; more frequent errors can lead to difficulty in understanding what the speaker says.
- Language Comprehension: the understanding of words and sentences. Difficulties in comprehending what others say can result in a failure to follow directions, to provide appropriate responses to questions, and to understand both spoken and written material.
- Language Production: the ability to use words and sentences to express meanings. These disorders can result in difficulties in both social interactions and academic and vocational activities.
- Pragmatic Communication: Children with disorders in this area may have large vocabularies and use complex sentence types, but may have difficulty following

the rules of conversation, such as taking turns appropriately, maintaining conversational topics introduced by others, and giving the appropriate amount of information (not too much, not too little) based on the conversational partner's needs and interests. These deficits can result in rejection by peers and attributions of "rudeness" by others.

Screening involves the collection of data to decide whether there is a strong likelihood that an individual has a problem that will require a more in-depth assessment. An appropriate speech-language screening measure is one that meets high levels of psychometric criteria, including well-established reliability, validity, sensitivity, and specificity, as well as assessing relevant areas of communication. A well-designed screening measure will look beyond a single area of concern; for example, it will examine both the child's expressive ability, as well as the understanding of language. Failure to achieve a criterion level on a screening measure should result in a child's referral for evaluation and more in-depth assessment. Some examples of language screening measures appear in Table 4.5.1.

EVALUATION

Review of existing and/or historical data is typically the first step of the evaluation process. Information can be gathered from parent interviews, teacher report, clinical observations, previous testing, and/or data kept on intervention progress from either internal (e.g., school; Birth to Three services) or external sources (e.g., medical records). When gathering this information, the team must determine what is known about the child versus what needs to be learned in the current evaluation to establish risk factors, the presence and type of disorder, and to contribute to the development of a treatment plan. The following are examples of basic questions to consider when gathering this initial information regarding a child's communication:

1. Reason for referral (e.g., who referred the child; what are the concerns regarding the child's current speech, language, and communication skills; when did the problem begin; impact of problem across settings)
2. Speech and language development (babbling by 10 months; first words by 18 months; two-word combinations and following simple directions by 24 months; sentences by 3 years); moreover, for those children who already received early intervention services, questions regarding their current mode of communication are asked: Are they using gestures, signs, communication devices or demonstrating pretend play skills?
3. Feeding (solid food by 6 months; using a cup by 18 months; drinking from a straw by 30 months)
4. Therapy (prior language evaluation/s; current and/or past intervention services)
5. Education (daycare; school; special education)
6. Birth/medical history (e.g., cleft lip; cleft palate; ear infections; PE tubes;

prematurity)
7. Significant family history (e.g., hearing; articulation; learning disabilities)
8. What does the family see as the child's most important problem in communication?
9. When did the problem begin?
10. Does this problem vary in terms of its severity or occurrence?
11. Can the child's speech be understood by people outside the family?
12. Can the child follow verbal directions at home or at school?
13. How does this problem influence the child's social communication across various environments, including school and within social settings?

TABLE 4.5.1

EXAMPLES OF SPEECH-LANGUAGE SCREENING MEASURES

Screening (Name/Author(s)/Date/Publisher)	Developmental Range
Battelle Development Inventory—2nd ed. Screening Test Newborg J (2005). Itasca, IL: Riverside Publishing	Birth–7:11 yrs

Screening Test for Developmental Apraxia of Speech: Examiner's Manual—2nd ed. Blakely RW (2001). Austin, TX: Pro-Ed	4–12 yrs
Adolescent Language Screening Test Morgan DL, Guilford AM (1984). Austin, TX: Pro-Ed	11–17 yrs

A common method for gathering this case history information is to ask families to fill out a questionnaire with queries like the above, prior to the evaluation session, and to conduct an interview with the parent at the time of the assessment to clarify and supplement the written information. *Caregiver information* gained through questionnaire and interview procedures can supplement results gathered from direct interaction between the clinician and child. Caregivers can provide information about the child's communicative functioning among a variety of contexts, including

home, school, and with peers. Caregivers can describe their own concerns by outlining the child's communication performance across these natural contexts. Parent report can give the clinician a better sense of the child's everyday communication challenges and areas of weakness. Sachse and Von Suchodoletz (2) support the validity of parent report measures in comparison to direct language measures (e.g., spontaneous language samples) when it comes to their young child's language skills and identifying potential delays. The advantages of parent report include the tendency for young children to be reluctant to interact with a clinician or in an unfamiliar environment. Allowing a child to play or converse with a parent, for example, provides a way for the clinician to observe the child's communication and interaction style indirectly, and may put the child and parent at ease. Additionally, parents may be reluctant or anxious to raise certain of their concerns or reveal specific information in direct conversation with an unfamiliar clinician. In order to decrease both caregiver and child stress, to minimize additional testing sessions, and to obtain a representative sample of the child's skills, gathering information from parents and caregivers as they both describe and interact with their child, can increase the efficiency of an assessment, as well as decrease the stress induced by long testing sessions. Some examples of parent report instruments appear in Table 4.5.2.

Once sufficient information about the history and the problem has been gathered, the team will determine the child's general developmental level to begin the evaluation process. Assessment of general developmental level, usually through psychological testing of cognitive and motor function, will help to establish the level of communication skills that might be expected, and help to select instruments that will target skills at the appropriate level. It will also be important to consider cultural and linguistic variables when planning the evaluation. Cultural variables to be considered may include child-rearing practices, ethnicity, rules of interaction, gender identity and socioeconomic status as well as linguistic variables such as oral, written, and manual languages used by the child and family.

A communication evaluation will usually include a battery of standardized assessments that provide an answer to the question of whether this child is significantly different from a sample of age-matched children whom the measure was normed in terms of the ability to speak, understand language, and use of speech and language to communicate with family, teachers, and peers. For this purpose, again, tests with strong psychometric properties must be chosen in order to answer the question in a fair and valid way. Some examples of tests often used for evaluation at various stages of development are listed in Table 4.5.3.

If testing confirms the observations of parents and teachers and corroborates the screening results that the child is showing difficulty with communication skills relative to others at his/her developmental level, the child can be identified as having a disorder in this area. However, not every child who tests low on a standardized test will be able to receive services for a communication deficit. Eligibility criteria

are based on local, state, and federal regulations determining the requisite level of impairment for services based on norm-referenced measures, observational assessment, whether the language impairment interferes with spoken language or primary mode of communication and whether the impairment affects the child's educational, social, or emotional development. Thus, one outcome of evaluation will be a determination as to whether a child's disability is severe or pervasive enough to qualify for publicly funded services. Clinicians need to be aware of local requirements for eligibility. If a child fails to meet eligibility criteria, parents may opt to obtain services privately.

TABLE 4.5.2

EXAMPLES OF PARENT REPORT INSTRUMENTS FOR COMMUNICATION

Parent Report Instrument (Name/Author(s)/Date/Publisher)	Developmental Level
Autism Diagnostic Interview—Revised Rutter M, LeCouteur A, Lord C (2003). Los Angeles, CA: Western Psychological Services	2–21 yrs

The Vineland Adaptive Behavior Scales—2nd ed. Sparrow SS, Cicchetti DV, Balla DA (2005). Bloomington, MN: Pearson, Inc.	Birth–90 yrs

In addition to establishing eligibility for services, the evaluation process is aimed at integrating data from the various professionals on the team in order to arrive at a diagnostic label that best describes the child's conditions. Communication disorders are very frequently associated with a variety of conditions, as Chapter 5.2.4 explains. So although failure to talk or poor speech development is frequently a child's presenting problem, it is often the case that evaluation uncovers deficits in other areas of development, such as cognition, hearing, motor or social skills that contribute to the choice of diagnostic label. When this happens, the child may receive a primary diagnosis of intellectual disability, autism, or hearing impairment, with language described as a secondary or comorbid condition. The conferring of a

primary diagnosis other than language disorder, however, does not mean that the child's need for communication assessment and intervention diminishes. Even when a child's primary diagnosis is something other than a specific speech or language disorder, assessment of communication strengths and needs remains important in order to develop an intervention program that will address all of the child's developmental concerns.

TABLE 4.5.3

EXAMPLES OF COMMONLY USED GENERAL LANGUAGE TEST BATTERIES

Test Name, Author(s)/Date, Publisher	Developmental Level

Woodcock Language Proficiency Battery—Revised. Woodcock RW (1991). Chicago, IL: Riverside Publishing	2–95 yrs

One additional issue explored by the evaluation team concerns the nonverbal child. Children may fail to acquire expressive language function for a variety of reasons, primarily because of neuromotor deficits that affect vocal function, such as cerebral palsy. However, some children without diagnosable neuromotor disorders may also fail to begin speaking during early childhood; children with Down syndrome and autism can sometimes show this pattern, for example. When this is the

case, the SLP will be charged with deciding whether the child should be taught to use an alternative or augmentative communication (AAC) modality, such as sign language, picture exchange communication system, assistive communication application (e.g., such as those for iOS platform) or a designated speech generating device (SGD). Although the considerations that go into this decision are beyond the scope of this discussion (see (3) for further discussion), in general, SLPs will attempt to ensure that the child has some way to communicate with others if speech is not an accessible modality for the child (3). AAC may be provided on a short-term basis, until more usable speech emerges, or may be part of the child's long-term communication program. The SLP will attempt, in investigating AAC usage for a particular child, to identify the best match of a system to a child's developmental level and communication needs. This investigation may be expanded as part of the assessment portion of the team's activities.

ASSESSMENT

Once it has been determined that the child has a disorder that includes communication deficits, a detailed assessment of the child's functioning is undertaken. This process has three main goals: to establish the child's baseline level of communicative function, to identify goals for intervention, and to monitor progress within the therapy program. To achieve these aims, SLPs typically use a range of methods that include not only standardized tests, but criterion-referenced, observational, and dynamic procedures. Norm-referenced tests, or standardized instruments, are, as we have discussed, used to compare a child's skills to those of other children of similar age and background. These formal instruments have specific statistical properties that allow meaningful comparisons among children to determine if their functioning is significantly different from typical performance. Standardized tests are particularly useful in determining the existence of a communication disorder, and for establishing eligibility for speech and language services. That said, norm-referenced assessments are not designed to identify the specific behaviors that constitute the child's deficits; only whether or not the child's performance differs from developmental norms. Criterion-referenced assessments, on the other hand, do not provide statistical comparisons to other children's abilities, but rather determine whether the child can perform particular tasks deemed to be important for communication. Criterion-referenced assessments may examine specific forms of speech and language in more informal ways or in naturalistic contexts, without standardized rules and methods. Instead, the clinician can establish criteria and learn whether the child meets these particular milestones. Criterion-referenced assessments allow the clinician to individualize the assessment to examine targeted communication behaviors and are ideal for evaluating whether intervention methods have been successful or to monitor progress in a course of therapy. These methods can be developed by the clinician to

answer particular questions, such as whether a child understands past tense forms, whether a child can understand vocabulary related to a school curricular unit, or whether a child can participate in language arts assignments given by a particular teacher (4).

The assessment of communication, of necessity, involves some observation of what a child's communication is like in natural situations. It is important to supplement standardized tests with real-life measures for a reliable index of the child's communication in everyday interactions. Observational, or *authentic,* assessment allows for a closer look at a child's communication, by examining the child's spontaneous language use and understanding in contextualized settings pertinent to the child and provides a record of the child's growth in skills over time. McCauley (5) argued for the importance of supplementing standardized measures with authentic assessment due to the fact that norm-referenced testing, even when high sensitivity and specificity were present, nonetheless was inconsistent in identifying actual errors made in a child's spontaneous speech. Thus, to get a realistic perspective of a child's expressive functioning, and to determine appropriate goals for expressive language use, sampling spontaneous communication is an important part of assessment. A range of methods of analyzing spontaneous speech in children at all stages of language development are available, using both paper and pencil as well as automated methods making use of software packages that apply to samples transcribed with codes to indicate various semantic, phonologic, and syntactic features. Examples of these methods can be found in Paul and Norbury (4), McCauley (5), MacWhinney (6), and Miller and Iglesias (7).

Dynamic assessment, an additional nonstandardized form of authentic assessment, is specifically designed to take a closer look at what factors, supports, or modifications enhance the child's communication performance. Dynamic assessment is used to manipulate the linguistic context through the use of prompts, cues, or various scaffolds to determine what best supports positive changes in communication. In turn, dynamic assessment provides important initial information about what techniques or teaching styles may be appropriate for treatment. Moreover, dynamic assessment measures have been found to reduce test bias for children learning English as a second language (8). With emphasis on the learning process (test-teach-test) rather than what has already been learned, dynamic assessment is especially helpful in determining whether real communicative impairments are present in bilingual school-age children who may appear to show deficits due to their lack of experience in English, rather than due to inherent language learning problems (9).

Another form of dynamic assessment is use of the *Response to Intervention* (RTI) model of classroom instruction. RTI is aimed at determining whether a child's poor performance is due to limited previous exposure to the concept or skill rather than inherent learning problems. This is accomplished by carefully monitoring each

child's progress within a course of regular classroom instruction in language and literacy, identifying children who perform poorly on these ongoing assessments, and providing them with supplemental small group instruction to determine whether their response to this additional input allows them to catch up to classmates and go on to perform at grade level. Children who respond to this level of intervention are spared the experience of evaluation for, and possibly mistaken placement in special education. Those who do not respond to the initial intervention may be provided with some additional one-to-one instruction, before being referred for an evaluation for special educational needs. SLPs working in school districts using the RTI model may be called upon to collaborate and consult with classroom teachers in the development of progress monitoring and initial intervention, before determining whether a child meets criteria for services in language and special education (10).

Having examined the range of methods available for assessing communication skills, we can now discuss the three major aims of the assessment process: establishing baseline function, identifying goals for intervention, and monitoring progress in therapy.

Establishing Baseline Function

The purpose of this phase of assessment is not merely to show that the child scores below other children on tests, but to document in detail the child's communicative strengths and weaknesses and whether there is a difference in how the child communicates across various contexts. Typically, a thorough assessment will include measures of both understanding and production of sounds, words, sentence structures, conversation, and storytelling. Profiles of relative strengths and weaknesses among these communicative skills will be used to decide on the child's overall level of communication, which will determine the goal level for areas that are less well developed. When determining the child's baseline level of communicative functioning, standardized tests can, again, be useful, especially those that focus on specific areas of function, rather than those in Table 4.5.3, which assess general receptive versus expressive skills more broadly. Some examples of these focused tests appear in Table 4.5.4.

TABLE 4.5.4

EXAMPLES OF STANDARDIZED TESTS FOR FOCUSED LANGUAGE ASSESSMENT

Test	Developmental Level
Boehm Test of Basic Concepts—3rd ed. Boehm AE (2000). San Antonio, TX: Pearson	K–2nd grade

Test of Word Knowledge. Wiig EH, Secord W (1992). San Antonio, TX: Pearson	5–17:0 yrs
Test of Written Language—4th ed. Hammill DD, Larsen SC (2009). Austin, TX: Pro-Ed	9–17:11 yrs

In addition to testing, though, SLPs often employ more observational methods to round out their picture of the child’s ability to communicate in real settings. Frequently, they collect a sample of the child’s communication as he/she engages in play or other age-appropriate activities with family or peers. These observations are aimed at discovering how the child uses the communication skills available to him/her to interact socially. Some children with very limited language can show strengths in using gesture, facial expression, and tone of voice to convey a range of meanings, while others at the same level of language show few of these abilities. Conversely, some children with nearly age-appropriate vocabulary and sentence structures who score well on standardized tests are nonetheless severely lacking in social communication skills, and this deficit would not be documented unless data from natural observation were collected. To that end, SLPs often collect samples of spontaneous communication in dyadic conversation. They may also sample the child’s ability to construct a coherent narrative about a set of pictures or by discussing a personal experience or retelling a favorite story or video plot. Narrative tasks are known to be highly related to success in school (11), and have been documented to represent weaknesses in children with various kinds of language problems (12). Thus, assessment of narrative skill is often an aspect of the communication assessment for language comprehension and production for school-age children. A range of methods are available in the literature for analyzing various

aspects of children's narrative production (4,9,11–14).

As noted earlier, assessment for baseline functioning can also involve answering questions such as, does this child communicate better with adults than peers? in structured or informal settings? in familiar environments? To answer these questions, a child's communication may be observed in several settings and among different partners. The SLP may, for example, collect language samples of the preschool child playing with a parent and then with a peer, of a toddler playing with a parent and then with a clinician, or of a school-age child having a conversation with a clinician and then telling him/her a story. By taking several observations in varying contexts, a fuller picture of the child's relative strengths and needs can be drawn.

Identifying Goals for Intervention

The completion of a comprehensive communication assessment leads to the identification of appropriate targets for a child's intervention program. Criterion-referenced, dynamic, and observational assessments are central to this aim. The SLP uses these methods to determine where a particular child is in the developmental sequence of communication acquisition, what skills are next in the developmental sequence of language acquisition, and what components and subcomponents of the language system the child has mastered, is using inconsistently, or is not using at all. Observation and language sampling will be used to identify aspects of communication that are most troublesome in preventing the child from effectively communicating with parents, teachers, and peers. Criterion-referenced assessment will be used to fill out the picture of strengths and needs. Dynamic assessment or RTI will help to determine what kinds of supports, cues, prompts, and materials will be most facilitating for the acquisition of new forms. The end result of this phase of the assessment will be a set of long-term goals that state the desired changes in communication to be targeted over the next 1- to 3-year period (depending on the child's current age). Typically measurable annual goals are based on the child's needs and present level of performance and align along a developmental continuum or with grade-level curriculum. Based on the identified speech or language impairment, goals are created to address identified impairment with speech production (e.g., articulation, phonology, fluency) or language: form (phonology, morphology, syntax), content (semantics), and/or use (social communication). Each long-term goal will be broken down into a sequence of short-term objectives, which state the steps the child will be led through in order to attain the long-term goal. Short-term objectives typically follow a three-part format:

1. "Do" statement: What the child will do to demonstrate achievement of the goal (James will produce sentences with "I want" and an object ["cookies"])
2. A context: Under what circumstances the child will be able to perform the behavior at this phase of the therapy (when shown a desired object and

prompted with "Tell me what you want")

3. A criterion: How frequently the child must perform the activity correctly in order to move on to the next step in the sequence (in 90% of trials).

Monitoring Change in Intervention

Once the basic plan of the intervention program has been designed, the SLP proceeds through each of the short-term objectives. In order to move on to the next step, however, the SLP must show that the child has achieved the criterion level stated in the short-term objective. Further, the SLP will need to document when the long-term goal has been achieved and therefore no longer needs to be addressed in therapy. These require tracking the degree to which the client is producing correct responses within and outside therapy sessions.

The child's intervention plans—the Individualized Family Service Plan (IFSP) intended for families of children from birth to three years of age or the Individualized Education Program (IEP) for school-age children—will specify how the child's progress on goals will be measured (e.g., given the category 'animals,' the child will name 4-5 animals, after exposure to animal names and pictures in picture books presented by the clinician). SLPs routinely record and analyze client responses to therapy activities in order to document these changes. Monitoring change in intervention, however, not only requires that SLPs show their clients can get, for example, 90% correct responses in a treatment activity; they also need to show that these changes generalize to real conversation and interaction. To demonstrate these broader changes, SLPs often use criterion-referenced assessments, as well as language sampling. These assessment methods allow the demonstration of change not only in structured activities, but also in the real-world situations that determine a child's communicative competence.

SUMMARY

The assessment of communication is part of the larger process of diagnostic evaluation and educational planning that goes into determining the strengths and needs of children with disabilities. In conducting these assessments, professionals from a variety of disciplines collaborate to determine a child's diagnostic classification and eligibility for publicly funded services, to describe in detail the child's needs in all areas of functioning, to identify the most appropriate goals for an intervention program, and to monitor the program as it proceeds to ensure it is efficient and effective. SLPs typically function as members of an assessment team whose primary responsibility is to evaluate the child's use of communication. They use a variety of methods to achieve these goals, including standardized tests, criterion-referenced assessments, observations of authentic communication, and

dynamic methods to identify effective supports for learning.

CHAPTER 4.6 ■ STRUCTURED INTERVIEWING

ADRIAN ANGOLD, ELIZABETH JANE COSTELLO, AND HELEN EGGER

INTRODUCTION

Interviews are necessary tools for all forms of clinical medical diagnosis, and they have a singularly prominent position in psychiatry because of the lack of other "tests" for psychiatric disorders. All structured interviews used in psychiatry have their roots in the phenomenologic clinical interview, although different interviews take rather different routes in the standardization of the collection of phenomenologic data relevant to diagnosis. The questioning strategies involved now represent a mature technology, and the sometimes acrimonious methodologic debates that once characterized the field have been replaced by the recognition that each approach has advantages and disadvantages that must be weighed in selecting a structured interview for each individual application.

The Limitations of Unstructured Diagnostic Interviews

It has been known for a long time that clinical training is sufficiently varied that colleagues of the same discipline, working in the same establishment, are often unable to agree about an individual's diagnosis, even when presented with exactly the same information (1–4). An apparent difference in rates of schizophrenia between New York and London proved to be almost entirely due to differences in diagnostic criteria applied to observed phenomenology (5). Observations such as these motivated the development of the formalized sets of diagnostic criteria familiar to us today from the DSM-IV and ICD-10.

The literature on medical decision-making had already shown that clinicians suffer from a number of information collection biases: (1) They tend to come to diagnostic determinations before they have collected all the relevant information; (2) they tend then to focus on collecting information to *confirm* that diagnosis (confirmatory bias); (3) they tend to ignore disconfirmatory information; (4) they combine information in idiosyncratic ways; and (5) they tend to make judgments based on the most readily available cognitive patterns (the availability heuristic). Further problems arise because of a tendency to see correlations where none exist (illusory correlation), and to miss real correlations (6).

Added to all these problems is the fact that, even today, standard diagnostic manuals do not provide very detailed descriptions of how to assess psychopathology at the symptom level. All of the criteria for oppositional defiant disorder, for instance, begin with the word "often." But "how often is often?" There is a great deal of room for clinicians to adopt very different decision rules about when to regard

such symptoms as being present.

In the face of all these difficulties it became apparent that methods were required to standardize the collection, quantification, and combination of diagnostic information. As a result, all structured interviews aim to:

1. Structure information coverage, so that all interviewers will have collected all relevant information (both confirmatory and disconfirmatory) from all subjects.
2. Define the ways in which relevant information is to be collected.
3. Structure the process by which relevant confirmatory and disconfirmatory information is combined to produce a final diagnosis.

Early Structured Diagnostic Interviews

In the early days of structured interviews, it was supposed that *clinicians* would be using them, because it was felt that only they had the necessary training and experience to be able to decide about the presence or absence of symptoms, even when quite detailed definitions were provided. The interview schedule served as a tool to guide the clinician interviewer in determining whether symptoms were present, but the interviewer made the decisions, on the basis of information provided by the child or adult. Interviews of this sort, like the Present State Examination (7) and the Reynard (8) for adults, and the Isle of Wight interview for children (9,10), were the first to be developed, since they sprang naturally from clinical practice. They were called *semi*-structured because the interviewer was allowed latitude in the specific form of the questions used.

Although the PSE and Isle of Wight interviews were used extensively in community surveys, it was clear that the use of clinician interviewers created both logistic and budgetary problems. Large-scale epidemiologic studies, such as the Epidemiologic Catchment Area (ECA) studies (11) mandated the use of nonclinician ("lay") interviewers. Some felt that such interviewers would be incapable of making the judgments about symptoms; so, following methodologies used by political and marketing surveys, interviews were developed that required only that the interviewer asks a set of fixed questions in a preset order, and collects the simple answers to those questions. In such interviews, it is the *questions* put to the subject which are structured, and the interviewer makes no decisions about the presence of symptoms. Hence they came to be called *highly* or *fully* structured. The Diagnostic Interview Schedule (DIS) was the paradigmatic example of this sort of interview in adult psychiatry (12), while the original Diagnostic Interview Schedule for Children and Adolescents (DICA) was the first child-oriented example (13,14).

Emergence of the Diagnostic Interview with the Child

Until the late 1960s, interviews and questionnaires directed to a parent or teacher

about a child's behavior and *observation* of the child's behavior were the predominant methods of assessment in child and adolescent psychiatry. Verbal information from the child was typically regarded as being only supplemental, or material for psychodynamic interpretation (15). More attention was paid to playing with the child than to the collection of information through direct questioning. In 1968, a key transitional paper reported on the reliability and validity of the Isle of Wight interview with the child (9). Here the behavior of the child in a face-to-face interview was examined directly, but little was made of the factual content of the child's reports. In 1975, Herjanic and her colleagues (16) asked: "are children reliable reporters" of factual information, and presented evidence that they are. Since then, a great deal of work has confirmed the importance of children's self-reports as a source of factual information, with the result that fact-finding (as opposed to interpretative) interviews with both parents and children are now regarded as being of equal weight in the diagnostic process, at least from late childhood (prior to about age 9, children are incapable of completing such "adult-style" interviews). The one exception is in the evaluation of attention-deficit hyperactivity disorder (ADHD) symptoms, where child reports have been found to be of little help (17,18). Even here, however, the recent growth of interest in ADHD in adolescence and adulthood has led to the development of new measures in this area (e.g., 19).

Disagreement among Informants and Its Implications

Until the 1980s, agreement between child and parent reports of symptomatology was widely regarded as being a test of the *validity* of *child* reports (9,14). However, it soon became apparent that only low levels of agreement among informants (correlation coefficients around 0.3 for agreement among children, parents and teachers) could be expected (20,21). It is now considered that low levels of agreement among different informants about the child's clinical state are to be expected and do not invalidate the reports of any of them. Rather, each key informant presents a particular view of the child's problems. Indeed, it is precisely because agreement among informants is low that multiple informants are needed. Were agreement very high, taking the history from more than one informant would be redundant.

The problem is that disagreement among informants means that one has to decide how to weight the information from each informant in arriving at a diagnosis. Since it is uncommon for informants to invent fictitious symptoms, the simple rule of regarding a symptom as being present if any informant reports it usually suffices. When symptoms are combined to make diagnoses, the usual procedure is to ignore the source, and to add up all positive symptoms from any source. Thus, a diagnosis of a major depressive episode (which requires the presence of at least five symptoms) might be made on the basis of three relevant symptoms being reported by the child

(say depressed mood, anhedonia, and excessive guilt), with two other relevant symptoms (perhaps sleep and appetite disturbances) being reported by another informant (typically a parent and/or teacher). Although some interview developers have recommended "reconciliation" discussions involving the interviewer, the parent, and the child to clear up discrepancies between their reports (22), such a discussion is problematic. Reconciliation requires one informant to modify his or her story, but that means admitting being wrong, or at least uninformed. The knowledge that such a discussion will occur could cause informants (e.g., drug-using adolescents) to withhold important information that they did not wish other informants (such as their parents) to hear about. Finally, in most research applications, one wishes to assure informants that what they say will not be revealed to anyone else, in which case a reconciliation interview is ruled out.

The remainder of this chapter is concerned with the description of key points relating to general psychiatric diagnostic interviews, that is, those that cover a broad range of the common disorders of childhood and adolescence. A number of interviews and observational systems exist for more specialized tasks (for instance, the Autism Diagnostic Interview and the Autism Diagnostic Observation Schedule (23,24)), but such instruments will not be considered further here.

A TYPOLOGY OF INTERVIEWS

As we have already seen, a distinction between semi-structured and highly structured interviews has found its way into the description and discussion of diagnostic interviewing techniques. However, these terms are not very helpful for two reasons. First, they imply that the key difference between different types of interview concerns the *amount* of structure they impose. The problem is that the real issue is not one of amount of structure, but rather who makes the final decision as to whether a symptom is present.

Respondent-Based Interviews

In interviews where the questions are absolutely prespecified, it is the respondent who makes the final decision (typically by answering yes or no to each question). The interviewer makes no such decisions, but merely reads the questions. Since the decisions as to the presence or absence of psychopathology lie with the respondent in such interviews, we refer to them as being *respondent-based.* The Diagnostic Interview Schedule for Children (DISC (25)) and the computer-assisted version of the DICA (26), and the Dominic-R (27) are the three representatives of this approach.

Interviewer-Based Interviews and Glossary-Based Interviews

We call interviews that require the interviewer to make an informed decision based on what the respondent says *interviewer-based.* The interviewer is expected to question until s/he can decide whether a symptom meeting the definitions provided by the interview (or known to them from their training) is present. This group of interviews includes the Anxiety Disorders Interview Schedule (ADIS (28)), the Child and Adolescent Psychiatric Assessment (CAPA (29)), the Child Assessment Schedule (CAS (30,31)), the paper and pencil (not the computerized) versions of the DICA (26) and its close relative the Missouri Assessment of Genetics Interview for Children (MAGIC), the Interview Schedule for Children and Adolescents (ISCA (32)), the various versions of the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS (33)), and the Pictorial Instrument for Children and Adolescents (PICA-IIIR (34)). Three of these interviewer-based interviews (the K-SADS-P IVR, the DICA, and the CAPA) provide extensive sets of definitions of symptoms and/or detailed guidance on the conduct of the interview, and we call these *glossary-based.* Such glossaries are particularly important when an interviewer-based interview is to be used by nonclinician interviewers because they provide detailed guidance as to what the interviewer is supposed to be looking for in making symptom ratings. Nonclinician interviewers have been shown to be able to make such "clinical" judgments with high reliability when they have received adequate training with such glossaries (35).

The distinction between interviewer- and respondent-based interviews is not hard and fast in actual practice, because there has been considerable cross-fertilization between these approaches. For instance, the CAPA, which has its roots in the interviewer-based tradition, includes a subset of questions that are to be asked verbatim of all subjects, as in a respondent-based interview, but then allows further questioning for clarification. On the other hand, the DICA, which had previously been a respondent-based interview, now requires interviewers to question much more flexibly, and is now an interviewer-based instrument (26). Though the distinction between interviewer- and respondent-based interviews provides a useful rough-and-ready typology, it is really better to consider interviews as lying at various locations along three dimensions: (1) degree of specification of questions, (2) degree of definition of symptom concepts, and (3) degree of flexibility in questioning permitted to the interviewers. Interviews that provide extensive definitions and require interviewers to make judgments lie in the interviewer-based region of that three-dimensional space, while those that specify every question and allow no interviewer deviation from those questions lie in the respondent-based region.

PICTORIAL INTERVIEWS

More recently, respondent-based child self-report interviews that add *pictorial* cues have been added to the assessment armamentarium. The most developed pictorial interview at this time is the Dominic-R (27,36,37) which is intended for use with 6 to 11 year olds. Pictures representing psychopathology relevant to seven diagnoses are shown to the child, and questions about whether each symptom is present are read at the same time. Because no frequency, duration, or onset data are collected, it is not yet clear how such information should be combined with diagnostic information from other sources. This is, however, a general problem for interviews with younger children, because before the age of 8 or 9, they simply cannot provide all the frequency, dating, and timing information that full diagnostic interviews require. Although diagnostic test–retest reliabilities cannot be reported for the Dominic-R, its item reliabilities are respectable in comparison with those reported from studies of older children with other interviews.

The PICA-IIIR, for children aged 6 to 16, adopts a somewhat similar approach, but the questions to be asked with the pictures are more loosely specified, and it is intended to be used by clinicians. It covers a broader range of diagnoses than the Dominic-R, but no test–retest reliability data are yet available (34).

Parent-Only Interviews for Younger Children

Standard practice in adult psychiatry is to rely upon a single key informant for structured diagnostic interviews. The person who is the subject of the interview alone is interviewed. Parent and teacher interviews are added in child and adolescent psychiatry because the child him/herself is regarded as being a limited informant. The point is that, at any age, interviews need to be conducted with whoever is needed to provide adequate reliable information coverage. We have already noted that younger children cannot provide all the information necessary for making DSM-style diagnoses, but there is no reason why the child's lack of capacity in this regard should invalidate the use of the available best informants (parents and sometimes teachers) for diagnostic purposes. After all, in clinical practice diagnosis for young children is very largely based on parent reports of the child's behavior supplemented by office observations and teacher reports. Following this logic, several groups have modified interviews originally developed for use with parents of older children to allow structured diagnostic assessments down to age 2 (38–40). A test–retest study of one of these (the Preschool Age Psychiatric Assessment [PAPA]) suggests that preschoolers' diagnoses assessed in this way are just reliable as those of older children (38).

Screened Interviews

The Children's Interview for Psychiatric Syndromes (ChIPS (41)) was designed as a *screening* tool covering 20 DSM-IV Axis 1 disorders. "Cardinal questions" concerning symptoms most often seen in children with a particular disorder are asked at the beginning of each section. If the answers to these screening questions are in the negative, then the rest of that section is skipped. No test–retest reliability data are yet available for the ChIPS. A similarly screened version of the CAPA is also available, but in practice, it has been found to save only about 10 minutes of interview time, so the loss of information resulting from not asking about all symptoms may not really be worth the time saving.

Computerized Interviews

Computer-*assisted* psychiatric interviews (CAPI) employ an interviewer to read questions from the screen and enter the appropriate codes into the computer as the interview progresses. The machine takes the interviewer to the appropriate stem questions, and stores the responses in a database. There is no need for bulky interview schedules to be copied and carried around, and data entry is completed during the interview (or during coding of the interview later in the office with some interviews). Furthermore, the computer will not accidentally skip parts of the interview, or accidentally vary the order of its presentation. On the other hand, computerized interviews can be programmed to vary the order in which sections are presented deliberately, so as to reduce the order of presentation effects observed when respondents learn that saying no tends to shorten the interview. However, interviews for use with children do not currently incorporate this potential feature. Recent advances in programming technology for structured interviews mean that even the most "interviewer-based" interviews can now be produced in CAPI formats. For instance, the CAPI version of the PAPA allows interviewers to write and store text notes with a stylus on a tablet PC; similar versions of the CAPA and YAPA are also available. When some interview schedules run to over 300 pages, the costs of buying computers can soon be offset against savings on schedule reproduction and data entry. The DISC has become progressively more complex over the last 20 years (largely because of the ever-increasing complexity of the DSMs), and, except as discussed below, the DISC-IV is now supposed always to be completed in its CAPI format, because it is really too difficult to administer it effectively in a paper-and-pencil format. There is also a CAPI version of the DICA, but this differs from the paper-and-pencil version of the interview in being fully respondent-based (42). Given the advantages of CAPI administration, we predict that paper and pencil will soon disappear as a means of interview administration.

The next level of computerization is referred to as *audio computer-administered* survey interviewing (ACASI). Here no interviewer is used at all. Rather, digitized

audio recordings of the questions (sometimes even with digitized video of an interviewer) are played back by the computer as the written form of the question is displayed. The respondent enters a response to the question, which is saved to the database. Obviously, such an approach can only be adopted with a respondent-based interview, and the DISC provides the paradigmatic example of this approach (43).

INTRODUCTION TO THE INTERVIEWS

Here we present a brief introduction to each of the diagnostic interviews, with a focus on their characteristic *response formats.*

The Schedule for Affective Disorders and Schizophrenia for School-Age Children (Kiddie-SADS, K-SADS)

The K-SADS "family" of interviews consists of a group of very diverse assessments. Indeed, the only features that all of the current versions of the K-SADS share in common are the name, the ability to make DSM-IV diagnoses, and the fact that all were designed to be administered *by clinicians.* The original version of the K-SADS (the K-SADS-P (44)) was a downward extension of the adult Schedule for Affective Disorders and Schizophrenia (SADS) and focused on the Research Diagnostic Criteria (45). Note that the "P" in its title stands for *present* (not parent). It was designed for use with children aged 6 to 17, but covered only a relatively limited range of symptoms and diagnoses. It was revised to cover DSM-IIIR (46) and DSM-IV.

K-SADS-P IVR

The version of the K-SADS-P most recently developed by Ambrosini and colleagues (46) is called the K-SADS-P IVR. This version is closest conceptually to the original K-SADS-P in including quite detailed definitions of severity codings for each symptom. The modal form for these symptom codings is a six-point scale, involving judgments about various combinations of intensity, duration, frequency, environmental responsiveness, psychosocial impairment, and observed behavior.

K-SADS-E

The K-SADS-E (47) (E for epidemiologic) collects ratings of the present episode of any disorder *and* the *worst* past episode. This interview was never even remotely similar in format to the K-SADS-P, because it rated only the presence or absence of symptoms, rather than employing the carefully defined severity codings of the K-SADS-P. The latest edition is DSM-IV compatible, and allows the current *episode* (not individual symptoms) to be rated as mild, moderate or severe.

K-SADS-PL

A group in Pittsburgh has developed the K-SADS-PL (present and lifetime), as a sort of cross between the K-SADS-P and the K-SADS-E (48,49). Symptom ratings have been reduced to three-point scales (typically not at all, subthreshold, threshold), and fairly minimal anchoring definitions of each point are provided. An initial 82-item screen interview, which allows skipping of substantial symptom areas, is also available.

WASH-U-KSADS

Rather brief definitions of symptoms are given, and level of severity is coded, but the severity codings are idiosyncratic, and bear little relation to those in other versions of the K-SADS.

COLUMBIA K-SADS

The symptom "definitions" provided are often simply restatements of the DSM-IV criteria. Sometimes (particularly in relation to depression) a little more guidance is given. Symptom severity is typically rated on what appears to be a six-point scale like the K-SADS-P and K-SADS-P IVR, but closer inspection reveals that two of the points are usually defined only as being intermediate between two other points. Thus, only four points (one being symptom absence) are really defined.

Although K-SADS interviews were developed for use by clinicians, some have also been used with lay interviewers (31).

The K-SADS family differs from most interviews (but not the ISCA) in directing that the parent should be interviewed first and then the child should be seen by the same interviewer, who is then expected to resolve any discrepancies between the child's reports and those of the parent. The interviewer then completes a record representing his/her summation of the two interviews. This procedure is highly dependent on clinical judgment, and means that the process of combining the information is not structured. It also seems likely to bias the results of the interview in favor of the parental reports, and some workers have instead scored the interviews with the parent and the child separately (50).

The Child and Adolescent Psychiatric Assessment (CAPA) and Its Congeners

The CAPA is one of an integrated group of instruments developed to assess a variety of risk factors for, manifestations of, and outcomes of child and adolescent psychiatric disorders. In addition to the usual symptom and impairment assessments,

it also includes extensive ratings of the family environment and relationships, family psychosocial problems, and life events (including traumatic events and physical and sexual abuse). A separate module called the Child and Adolescent Impact Assessment (CAIA (51)) measures the impact of the child's problems on the family, while the Child and Adolescent Services Assessment (CASA (52,53)) covers service use for mental health problems in multiple sectors and settings. Psychosocial impairment in 17 domains of functioning is measured at both the syndromic level and overall. In the interview with the child, 62 items reflecting the child's observed behavior during the interview are also coded. In order to facilitate completion of the interview by nonclinicians, the CAPA provides a more molecular approach to symptom codings. Extensive symptom definitions are given in a glossary and on the schedule, and rules are specified to allow nonclinicians make separate codings of the intensity, frequency, duration, date of onset of symptoms, and psychosocial impairment resulting from them. The CAPA emphasizes getting descriptions and examples of possible pathology to ensure that codings are not based on the informant's misunderstanding of what was being asked about (35,54,55).

A version of the CAPA has been developed for use with *young adults* (the Young Adult Psychiatric Assessment, YAPA), and a substantially modified version is now available for use with the parents of preschool children (PAPA (38)). The latter includes assessment of a number of areas of particular relevance to preschoolers that are not included in any other diagnostic interview. In addition, a version of the CAPA with empirically derived screen items is available, which allows sections to be skipped if screen symptoms are absent. A streamlined version of the CAPA for collecting data for twin studies has also been developed (56).

Diagnostic Interview for Children and Adolescents

The DICA started out as a respondent-based interview over 20 years ago (16,42,57,58). Since then it has been progressively modified so that its paper and pencil version is now an interviewer-based interview (26,59,60). However, there is also a computer-based version of the DICA that remains fully respondent-based (26,60). In addition, the group responsible for the development of the DICA has produced a modification called the Missouri Assessment for Genetics Interview for Children (MAGIC). The major difference between the DICA and the MAGIC is that the MAGIC has a specifications manual, which includes a great deal of guidance on how to elicit key features of symptoms, and a variety of clarifications of coding instructions (26).

The DICA and the MAGIC provide alternate versions for self-reports from children aged 6 (or 7) to 12 and 13 to 17, which have differently worded questions. The DICA has also been used with even younger children, but special training is required for its administration in those under 6 or 7, and the instructions to

interviewers essentially tell them to ignore the usual questioning format laid out in the schedule and use their own questions.

Symptoms are typically coded on a three-point scale (no, sometimes/somewhat, yes) for items about emotional symptoms, and a two-point scale (no, yes) for disruptive behaviors with additional information on frequency sometimes being added. Impairment is measured at the syndrome level by three items asking about symptoms making it hard to "get along" with the family, friends, and at school, rated on four-point scales (not at all, not too much, somewhat, quite a bit).

CHILD ASSESSMENT SCHEDULE

The CAS is organized around thematic topics and provides ratings of many items that are not required if all one wants to do is make ratings of the DSM criteria for disorders (31,61–64). The CAS now exists in child (7–12), adolescent, and parent report versions. Although originally developed for use by experienced clinicians, the CAS has now been used by lay interviewers in several studies. Symptoms are scored on a four-point scale (yes; no; ambiguous; not scored). This is followed by questioning about the onset and duration of positive symptoms. The items to be coded are defined in brief sentences which outline each symptom concept. The interviewer is expected to make a judgment about the coding based on the answer to the questions on the schedule (plus any additional questions that may be thought necessary).

The CAS also has a 56-item section for recording observations of the child's behavior during the interview. Diagnoses can be generated manually by interviewers using algorithms provided by the developer of the interview, but computerized scoring is recommended. The algorithms also generate symptom scales pertaining to a number of areas of psychopathology.

Psychosocial impairment is measured using a separate measure, the Child and Adolescent Functional Assessment Scale (CAFAS), which can also be used alone or with another diagnostic interview (65–67).

The Anxiety Disorders Interview Schedule

Notwithstanding its title, the ADIS also provides brief ratings of symptoms pertinent to other disorders, but its coverage of the anxiety disorders is more thorough (68–73). The interview is designed for clinician use, and was derived from the adult ADIS (74). Questions that *should* be asked are provided, and guidance is given about when to use additional questions. Most symptoms are scored on a simple three-point scale (yes, no, other). However, in the anxiety section a good deal of use is also made of nine-point scales (represented by a thermometer) ranging from not at all to very, very much. Similar scales are used to rate "interference," which is the ADIS term for psychosocial impairment resulting from disorders. Skip structures are

frequently employed, so many individuals will not be asked about all symptoms.

The Interview Schedule for Children and Adolescents

The ISCA mandates administration by experienced clinicians with extensive structured interviewing training, and full understanding of the principles of diagnosis and its application to children with psychopathology. Interviewers must be able to combine the symptom information from both parent and child into diagnoses themselves, since formal algorithms for this process (other than the official diagnostic manual itself) do not appear to be available (32). Questions are clearly specified, but much additional clarification is expected of interviewers, who are not expected slavishly to stick to the written questions. Sixty-nine "major" symptoms plus 10 "mental status" items are covered, and typically coded on a nine-point severity scale that incorporates judgments about associated distress, functional impairment, and the amount of effort required to counteract symptoms. "Subsidiary information" about many symptoms is also collected, typically in a yes/no format. In addition, 17 intra-interview behavioral observation items are assessed.

A version of the interview for use with young adults (the Follow-up Interview Schedule for Adults, FISA) has also been developed.

The Diagnostic Interview Schedule for Children (DISC)

As already indicated, the questions on a respondent-based instrument are designed in a fixed, ordered sequence, and require very simple responses (typically yes/no, or picking one from a set of multiple choices for frequencies and durations of symptoms). Symptom severity is defined by similar yes/no answers on subsidiary questions (asked only if a positive response was obtained to a superordinate question) and forced choices from short sets of frequency ranges. All data combination is performed by computerized algorithms. The DISC covers a wide range of childhood and adolescent disorders and is suitable for use with 9 to 18 year olds (75). A version for use with the parents of preschoolers is currently under development. CAPI and ACASI versions are available.

INTERVIEW TIME FRAMES

The K-SADS interviews, the ADIS, the CAS, the Dominic, the PICA-IIIR, and the ISCA all focus on the child's current status or the current episode of disorder, though the definition of "current" is largely unspecified, except in the case of the ISCA, where the assessment period is specified (e.g., 2 weeks for irritability). The Columbia K-SADS adds a past 2-week time frame to the current frame. The K-SADS-PL, the Columbia K-SADS, and K-SADS-E also explore lifetime histories of

"worst" episodes, while the ISCA also provides for assessment of lifetime disorder, and an interim version provides an assessment of current status plus the child's status in the interim between the current assessment and the last assessment for use in follow-up studies. The DICA and MAGIC focus on the whole lifetime, but for some disorders an additional shorter time frame is also included. For instance, in the depression section, the MAGIC asks about the past month as well as whether the child has "ever" had symptoms. The CAPA covers a "primary period" of 3 months, but also notes whether certain uncommon symptoms (such as suicide attempts) have ever occurred, and a version that provides lifetime coverage of major episodes of certain syndromes is also available (56). The full DISC-IV can be used to assess either the last month or the last year, and also offers a module to determine whether certain syndromes that did not occur during the preceding year had occurred at any point since the age of five.

SPECIFICATION OF QUESTIONS, INTERVIEWER FLEXIBILITY, AND DEFINITION OF SYMPTOMS

In a fully respondent-based interview like the DISC, or the computerized version of the DICA, all questions are completely specified and no others may be used. There is no interviewer flexibility, and no need to provide definitions of symptoms. All variability in these features concerns the interviewer-based interviews.

The ADIS, CAPA, DICA, and MAGIC all contain questions that, under most circumstances, should be asked as written in the schedule. Additional questions are then asked as necessary to allow the interviewer to determine exactly whether the symptom is present. Many such questions are provided on the schedule of the CAPA, a smaller number is provided by the CAS schedule (but it is not clear to what extent the "set" questions of the CAS are mandated for use). Most guidance on this process for the DICA and MAGIC is provided in the MAGIC's specifications manual. All these interviews provide at least some additional instructions about when to probe further. The K-SADS group of interviews provides a range of suggested questions, but no formal rules about when they are to be used or skipped. Interviewers are also expected to ask any additional follow-up questions that may be necessary to clarify responses.

By interviewer flexibility, we mean the degree to which the interviewer is expected or encouraged to use judgment in asking additional clarifying questions. In this respect, the K-SADS and ISCA (and perhaps the ADIS) interviews may be seen as providing most flexibility because they demand that judgments based on clinical experience be made, and in the case of the K-SADS do not mandate the use of any particular questions. The problem question is "flexible to do what?" The answer is relatively clear in the case of the K-SADS-P IV and the CAPA, where detailed coding rules are provided for each symptom. The task of the interviewer is to

determine whether those coding criteria are met. With the other interviewer-based instruments it often seems that the interviewer's job is to get the answer *to the original question.* Variable amounts of guidance on how to do so are provided; in considerable detail in the MAGIC specifications manual, with brief symptom definitions in the CAS, but little or no guidance in the K-SADS-E or ADIS.

The K-SADS-P IV and the CAPA provide detailed *definitional* glossaries covering each symptom, which means that the task of the interviewer is quite clearly specified at the level of the definition of symptoms. The CAPA glossary also contains many procedural instructions relating both to questioning in general and questioning about specific symptoms; but these are presented as being secondary to the definitional issues. The MAGIC specifications manual can also be seen as being a glossary, but it is, first and foremost, a *procedural* manual. It is primarily about how to collect the information. In the course of this discussion of procedure, it also includes a good deal of definitional material, but does not provide formal definitions of items in the way that the K-SADS-P IV or CAPA do.

RELIABILITY OF STRUCTURED DIAGNOSTIC INTERVIEWS

A difficulty with the literature on "reliability" is that the term is applied to several very different sorts of design and statistical approaches. Three of these are commonly seen in the literature on structured interviews, but only one presents a useful test of what one ultimately requires in a diagnostic interview. For instance, one often sees reports of *interrater* reliabilities in the interview literature. However, interrater reliability is not a very useful index of interview performance. With respondent-based interviews it tests nothing but whether one interviewer can read aloud adequately while another codes a schedule. With such interviews, if interrater reliability is not in the high 0.9s, one should retrain or fire one's interviewers! In an interviewer-based interview, the questions are not fixed, and so different interviewers could use different questions to elicit the same information. Since the interrater reliability paradigm uses multiple raters to score the same interview, this major source of potential unreliability is eliminated, with the result that the interrater reliability is likely to substantially overestimate the reliability of the interview in actual use. However, if interrater reliabilities fall below about 0.8, that is an indication that something is either wrong with interviewer training, or that the interview needs to be revised to provide greater clarity about what is supposed to be rated. The point is that, if very high interrater reliability coefficients cannot be obtained, we can be certain that test–retest reliability will be poor.

"Internal reliability" is sometimes reported for scales resulting from diagnostic interviews. Typically the statistic given is Cronbach's alpha. This statistic provides a measure of the degree to which the items in the scale are correlated with one another. There are two problems with the use of such a statistic here. First, it has

nothing to do with whether *raters* are coding items “reliably”; it concerns the degree to which the items in a scale are all measuring the same thing. Second, a perfectly good diagnosis could be associated with low correlations among the symptoms that signal the presence of that diagnosis. Most medical (and psychiatric) diagnoses are more concerned with pattern recognition than with scalar values. For instance, in the general population it is unlikely that dry eyes, dry mouth, and arthritis are very highly correlated with one another, but that does not mean that Sjorgren’s syndrome is a bad diagnosis. Of course, if the task is to develop a scalar measure of some construct, then the scale’s alpha is important information. However, from the perspective of a diagnostic interview, low alphas are not necessarily a bad thing, nor are high alphas necessarily a good thing. It is entirely possible to have a perfect measure of a diagnostic entity where Cronbach’s alpha for the symptoms constituting that entity was close to zero.

Table 4.6.1 shows the results of studies of the *test–retest* reliabilities (Kappas) of diagnoses measured by the instruments considered in this chapter. Test–retest reliability is what is needed in judging an instrument. In the absence of reasonable test–retest reliability, all other reliabilities are moot. It can be seen that all the interviews that have been tested do a reasonably good job, and that there is not much to choose between them. These reliability coefficients are similar to those reported for psychiatric interviews with adults.

Reliabilities for scale scores derived from the interviews are typically rather higher than they are for diagnosis, but that is nearly always true of comparisons between scale score reliabilities and the reliabilities of categories generated by imposing cut points on the same scales. It is also important to remember that some of the unreliability of diagnostic measures is the product of the diagnostic system itself, thanks to its requirement that numerous unmemorable details about past psychopathology be considered. Particular problems have been identified with the reliability of responses concerning the duration of symptoms and the dates of their onsets (76,77).

Despite enormous efforts on the part of interview developers, it cannot be said that the reliability of diagnostic interviews has increased much over the years. We now have a fairly mature interview technology which has been repeatedly refined in the hope of increasing the reliability of assessments. The current arsenal of diagnostic interviews probably offers as good reliability as can be achieved until quite different means of arriving at psychiatric diagnoses appear.

TABLE 4.6.1

DIAGNOSTIC TEST–RETEST RELIABILITIES (KAPPAS) OF INSTRUMENTS

	MDD[a]	Dysthy/Minor D	Any Depress	GAD/ OAD	Sep Anx	Specific Phobia	Social Phobia	Any Anx	PTSD
K-SADS-P	0.54	0.70						0.24

DISC-IV—combined P & C. Clinic sample. Chinese	0.61				0.53					(
DISC 2.3—combined P & C. Community sample	0.45			0.52	0.49		0.44	0.47		(

[a]MDD, major depressive disorder/episode; Dysthy, dysthymia; Minor, minor depression; Any Anx, any a
spot traumatic stress disorder; ODD, oppositional defiant disorder; SA/D, substance abuse or minor de
generalized anxiety disorder, OAD, over-anxious disorder; Sep, separation anxiety disorder; ADHD, atte
disorder; CD, conduct dependence.

A problem with the test–retest assessment of reliability is that it requires that the interview be repeated within a short period of time. With both questionnaires and interviews one typically finds that fewer symptoms are endorsed at the second interview than at the first (78,79). There are many possible explanations for this effect (80), but some evidence suggests that the results of the first interview are probably the most accurate representation of reality. The usual interpretation of test–retest reliability statistics such as Cohen's Kappa for categorical data (such as

diagnoses) and the intraclass correlation coefficient (ICC) for continuous data (such as scale scores) involves the supposition that the relationship between scores at the first interview and those at the second involves two components, agreement and random error. The presence of a *consistent difference* between first interviews and second interviews indicates that such statistics underestimate the "true" (and ultimately unmeasurable) reliability of both interviews and psychopathology scales.

VALIDITY OF STRUCTURED DIAGNOSTIC INTERVIEWS

The problem with trying to assess the validity of psychiatric interviews is that there is no noninterview test for most psychiatric disorders. The structured interview itself is now the closest approximation we have to a gold standard. So how are we to validate the diagnoses obtained from such interviews? This is a version of a problem that psychologists have been grappling with for decades, one that led to the concept of *construct validity*. The central idea here is that the validity of an instrument for the measurement of a psychological construct inheres not in some single agreement coefficient with one external standard, but in the instrument's performance within the *nomologic net* of theory and data concerning the construct or constructs that the instrument purports to measure (81–89). As Gulliksen (84) pointedly remarked over half a century ago, "at some point in the advance of psychology it would seem appropriate for the psychologist to lead the way in establishing good criterion measures, instead of just attempting to construct imperfect tests for attributes that are presumed to be assessed more accurately and more validly by the judgment of experts." Structured interviews were developed because of the dismal psychometric properties of unaided clinical diagnosis, so comparisons with unstructured clinical judgment (as might be found for instance in chart diagnoses) are hopelessly flawed tests of diagnostic interview validity. That has been obvious to interview developers for a long time, so "validity" studies have sometimes provided the clinicians with all the information from the interviews to be validated, in addition to allowing them to collect further information should they wish to. In such a circumstance it will often be the case that *most* of the information available to the clinician comes from the interview under test. It will hardly be surprising, then, if there is good agreement between clinician and interview, but no real test will have been done.

In considering the validity of any interview we should take a construct validation approach, and describe what we currently know about it in relation to the nomologic net pertaining to child and adolescent psychiatric diagnosis. So far, only the developers of the CAPA have explicitly laid out the evidence for the validity of the CAPA using this approach, but most of the interviews considered here can point to similar chains of evidence. To give a flavor of the sort of evidence relevant to construct validation, the following findings have been adduced as construct validators of the CAPA (29):

1. Diagnostic rates and age and gender patterns of disorder given by the CAPA are consistent with those found using other interviews.
2. Patterns of diagnostic comorbidity are consistent with those found by other interviews.
3. Symptomatic diagnoses are associated with psychosocial impairment.
4. Parent and child reports of psychopathology on the CAPA are related to parent and teacher reports of problems on well-established scales for detecting psychopathology.
5. Children with CAPA-identified disorders use more mental health services than children without diagnoses.
6. CAPA-diagnosed children tend to come from families with a history of mental illness.
7. There is genetic loading for a number of CAPA scales scores and diagnoses.
8. CAPA diagnoses show consistency over time.
9. CAPA diagnoses predict negative life outcomes.
10. Different CAPA diagnoses are differentially related to the physiologic changes of puberty.

There is, of course, a big drawback to this approach. No new interview will be able to point to such chains of evidence until it has been in use for quite a time. How then is any new instrument ever to be developed? The answer lies in the application of common sense and well-established assessment principles. When a new assessment is needed, it is perfectly proper to use the best available information about the nature of the phenomena to be measured to design what seems, on the face of it, to be an adequate measure. Attention needs to be given to keeping questions short, and focused on single constructs; to defining the task of the interviewer clearly; and to providing good definitions of the constructs to be studied in the case of interviewer-based interviews. If initial test–retest reliability is adequate, then in general, it is unlikely that the interview will prove to be completely “invalid.” Since it is very unusual to be trying to assess a construct that has been utterly unmeasured before, or about which nothing whatever is known, it will also usually be possible to include in the test–retest study other measures that will give some indication of the concurrent, predictive, or divergent validity of the new instrument.

ADVANTAGES AND DISADVANTAGES OF INTERVIEWER- AND RESPONDENT-BASED INTERVIEWS

Neither interviewer- nor respondent-based interviews are ideal tools, and there is simply no answer to the question “Which type is best?” In this section, we list the general advantages of each type of interview, and the lack of each advantage can be regarded as a disadvantage of the other type. However, it is worth noting here that it has sometimes been said that respondent-based interviews are more appropriate for

general population studies. Since it has now been shown that lay interviewers can provide reliable and valid ratings using interviewer-based interviews, this position is no longer tenable. Indeed a number of larger-scale longitudinal general population studies have used (and are still using) interviewer-based interviews (for instance) (90,91).

Advantages of Interviewer-Based Interviews

Interviewer-based interviews have four theoretical and practical advantages: (1) If the interview has been conducted and coded properly, the meaning of the ratings is precisely known; (2) they provide opportunities to cross-check discrepant or confusing information; (3) they enable the use of efficient open-ended questioning strategies, and allow the use of redundant questioning, which has been shown in adults to improve the quality of responses; and (4) they appear to be less prone to overdiagnosis on the basis of symptom reports, so arbitrary impairment scale cutoffs do not have to be employed to produce reasonable diagnostic rates in unselected community samples.

What Do the Codings Mean?

In an interviewer-based interview, a positive coding for a symptom means that it has been determined that the symptom as defined in the schedule is present. In a respondent-based interview, one knows only that a child or parent responded positively to a particular question. One does not know exactly what the child or parent understood the question to mean. This problem has been documented with unusual symptoms that most children never experience, such as obsessive–compulsive or psychotic symptoms. Such symptoms were greatly overreported using early versions of the DISC (92). When clinicians reviewed what the children said, it was obvious that what was being reported was not obsessive–compulsive disorder or psychosis. However, if an unstructured clinician review is added to the diagnostic process, one no longer knows exactly what factors went into the final rating, and one great advantage of the respondent-based interview is lost.

Cross-Checking Information

It is common in clinical practice to find that certain answers appear to contradict previously given information, or lead to uncertainty about whether a symptom is present. In an interviewer-based interview, one simply attempts to clarify the contradiction or confusion. The respondent-based approach provides no mechanism for resolving such difficulties, since interviewers are not allowed to exercise their judgment about such matters.

Use of Open-Ended and Redundant Questions

The distinction between open and closed questions is not absolute, but open questions are those that offer the chance to provide a wide range of answers or free-recall descriptions of phenomena, while closed questions call for one of a limited set of responses. For example, an open question in response to being told by a child that he had received a bad school report might be "How did you feel about your bad grades?," whereas "Did your bad grades make you feel unhappy?" would be a closed question. If a child had just admitted to stealing, responding with "Tell me more about that" involves an open question, whereas "What did you steal?" is a closed question. Basically, closed questions call for a yes/no answer or a date, frequency, duration, or other quite specific piece of information, while open questions give the opportunity for the child to provide a description of his feelings, which might or might not involve sadness or hostility. The work of Rutter and Cox and their colleagues offers some direct guidance on the best ways to use these different sorts of questions with adults, and in the light of the literature on children's memory, there is little reason not to use a similar approach with children (93–97). They concluded that, in general, most factual information was collected when a systematic approach that relied heavily on open questions was used. This approach was also conducive to parental expressions of emotion, since it involved less talking on the part of the interviewer and gave more time for parents to discuss their concerns. On the other hand, a noninterventionist approach resulted in the provision of less relevant information, while challenging interpretations and a confrontational style proved less effective in eliciting emotions. Thus, open questions can be effective in collecting information efficiently, but, of necessity, respondent-based interviews must rely on closed questions. On the other hand, closed questions are necessary to elicit information that is otherwise not forthcoming, and respondent-based interviews have been a substantial help to the developers of interviewer-based interviews in establishing well thought-out logic structures for series of closed questions.

A redundant question is one that is asked more than once in different ways; that is, questions that contain two presentations of the same item, as in "Have you been more irritable than usual?," followed by "or made angry more easily?" The adult survey literature (98) suggests that such redundancy is actually helpful in providing both additional time for thought and a second chance to pick up symptoms. If the answer to one question is positive and the other negative, then that is no problem for an interviewer-based interview, where follow-up questions can be used to clarify the situation. However, this cannot be done in a respondent-based interview, where specific chains of questions in response to initially discrepant information would be required. Collapsing the two questions into one is no help because this generates a "multiple question" which requires the respondent to remember and process the two parts of the question simultaneously.

Reasonable Rates of Disorder

Rates of diagnosis based only on symptom reports were found to be unreasonably high with early versions of the DISC. To correct this tendency, it is now usual to require that a diagnosis only be allocated when the score on the Child Global Assessment Scale (CGAS) is less than 60 (or sometimes 70; i.e., when notable psychosocial impairment is present). However, in most cases, the DSM-IV requires that *either* impairment *or* distress be present, not that significant impairment always be present. Furthermore, the typical impairment cutpoint of 60 was established because it generated what appeared to be sensible rates of diagnosis, not because anyone with a score over 60 is necessarily unimpaired. Since the K-SADS-P and the CAPA employ exacting definitions at the individual symptom level, community studies using these instruments do not need to apply additional rules about impairment to generate sensible rates of diagnosis.

Advantages of Respondent-Based Interviews

We can also identify three advantages of respondent-based interviews: (1) Less intensive training need be provided to interviewers, (2) a lesser degree of quality control is required, and (3) computer-administered (ACASI) interviews offer the prospect of providing a “preclinical” screening for use in clinical settings.

Intensity of Training

There is no doubt that an interviewer-based interview makes greater demands on an interviewer than does a respondent-based interview. For instance, training on the full CAPA package takes a month, compared with a few days for the DISC.

Quality Control

“Interviewer drift” occurs with respondent-based interviews, necessitating continuing quality control throughout a study, but it is unarguable that there is much more to check with an interviewer-based interview. Care must be taken, not only that the interview is being conducted and coded properly, but mechanisms must also be in place to ensure that interviewers continue to interpret the responses of interviewees correctly. Whether this additional burden is worth the effort depends on the situation in which the interview is being used.

Preclinical Screening

We have reached the point where it is feasible to have parents and children complete

a computer-administered diagnostic interview like the DISC-IV before they see a clinician at all. The possible output from the DISC-IV is almost infinitely flexible, and requires only programming to allow the production of reports tailored to particular clinical needs that can be generated as soon as the interview is finished. Equipped with such a report, a clinician familiar with one of the interviewer-based interviews would then be starting with a very respectable initial diagnostic formulation to guide further elucidation of the clinical status of the child. For instance, the ACASI version of the DISC has also been found suitable for use in juvenile justice settings where staff are rarely available to conduct diagnostic interviews.

SELECTING A STRUCTURED INTERVIEW

As we have already seen, reliability and validity quotients are little help in selecting the "best" interview, because there is little to choose between interviews in this regard. Similarly, all the interviews considered here take quite a long time to complete, and their length is proportional to the amount of symptomatology manifested by a child. None has been shown to be notably shorter than any other in practice, and so reported mean interview durations are also no help in selecting and interview for any particular application. Rather, the key to selecting an interview is to be very clear about what that application demands. This means having thought through what the ideal interview for that application would be like, so that the characteristics of each can be matched against those criteria. It is also worthwhile to prioritize these demand characteristics in advance. It may not be possible to have everything, so it is a big help to have thought through the relative impact of different tradeoffs. In the following sections, we consider some questions that prospective interview users should ask themselves as part of the process of selecting an interview.

1. *What content areas need to be covered?* All interviews do not cover all diagnoses (indeed, none covers all possibly relevant diagnoses). It is essential in the first instance to decide what areas must be covered, and what additional areas would be nice to have, but not essential.
2. *What assessment time frame is needed?* The addition of a lifetime frame involves either compromises in the assessment of current or recent symptomatology (as with the K-SADS-PL) or combining a short time-frame interview with a separate lifetime interview, which results in a very long assessment. If one is conducting a 3-month follow-up assessment following treatment, an interview that focuses on diagnostic status over the last year will not be very helpful.
3. *What sort of interviewers will be available?* In general, clinicians are not enthusiastic about using a respondent-based interview because they have to

follow a fixed schedule of questions, and it provides no means to collect more detailed information that may be relevant to a variety of treatment decisions. So it makes sense for them to use one of the interviewer-based interviews. Such interviews can also be very useful clinical training tools, since they provide excellent models for the clinical interviewing process.

If lay interviewers are to be used, then the K-SADS family of interviews may not be the best choice because these interviews have all been developed for use by clinicians and provide less guidance for the training of lay interviewers. No reliability data on their use with lay interviewers are available. On the other hand, the CAS, CAPA, DICA, and ADIS were all developed for use with trained lay interviewers and have been shown to have acceptable reliability in their hands; all of these interviews are also acceptable to clinicians.

4. *What is the age and developmental level of the children to be assessed?* It is clear that “adult-style” diagnostic interviews (all of the interviews considered in this chapter fall into this category) with preschool children are a waste of time, because they are cognitively incapable of providing all the information required by the DSM-IV or ICD-10 diagnostic criteria. Several groups are working on this problem at present, but none of the instruments reviewed here is of any use for interviewing very young children directly. The K-SADS and DICA are said to be suitable for face-to-face use with children down to the age of 6, but others doubt that a *full* diagnostic interview really works with children under the age of 8 or 9, unless the interviewer simply “goes off interview” to get a relatively impressionistic view of the child’s symptomatology. Even the interview with the parent requires substantial modification for preschoolers. We would not recommend the use of any of these instruments in face-to-face interviews with children under the age of 8 or 9. Picture-enhanced interviews like the Dominic-R may be suitable down to the age of 6, but even here, reliability appears to be somewhat lower with younger children, and such interviews do not generate full diagnoses. The same problem applies to older individuals with substantial intellectual deficits. When an individual’s IQ is much below 70, it becomes very difficult to complete a full diagnostic interview. Interviews with parents and teachers may still be conducted, but we know little about their performance characteristics in such circumstances.

   At the other end of the juvenile age range (late adolescence and early adulthood), the researcher or clinician has the choice of shifting to an adult measure, or using an age-appropriate modification of a child interview (such as the YAPA).

5. *How much can I afford to spend on training and quality control?* “Spend” here refers to both time and money. If less than a week is available, then none of the interviewer-based interviews is suitable, because good training for them demands a greater time investment. However, DISC training can be provided in as short a time as this, because the DISC requires far less of interviewers. On the other hand, when amortized over the life of a study or clinical program,

initial costs for training usually turn out to be only a small percentage of total costs, so training on an interviewer-based interview may constitute a good investment.

6. Once each interview is completed, the DICA and CAPA both expect that it will be reviewed for appropriateness of codings. In addition, regular (both recommend weekly) continuing training sessions for interviewers are required to prevent interviewer drift. Are funds and personnel available to support such continuing quality control and training procedures? The CAS and K-SADS interviews do not appear to have standard recommendations for quality control and continuing training, but there is no reason to suppose that data quality and consistency are any easier to maintain with these instruments. Since the DISC-IV is computerized, and the DISC interviewer's task is much less arduous than that required of interviewers using any of the interviews considered in this chapter, it demands less effort to control interviewer drift. However, interviewer monitoring is still necessary to ensure that interviewers are following the questioning rules exactly, and to ensure that they are actually conducting interviews and not simply falsifying them (yes, this does happen!).
7. *What needs and resources do I have for data entry and manipulation of the data?* The K-SADS family of interviews produces diagnoses through the medium of score sheets completed by the interviewer and scored by that person to produce diagnoses. The CAS provides formal algorithms for making diagnoses that can be implemented either by the interviewer or a computer. The CAPA offers only computerized algorithms because its developers (like those of the DISC) believe that the process of producing a final diagnosis from a large array of symptom data is of such complexity that errors are bound to occur if humans do it unaided. These different approaches to producing a final diagnostic formulation have very different implications for data entry and manipulation. If the computer is to make the diagnoses, then all the symptom information must be entered (this task easily runs to hundreds or thousands of variables per case), and diagnostic algorithms must be available. If the clinician makes the final diagnosis, then one could simply enter only that information (or not computerize any data at all in a clinical setting where the interview is being used just as a clinical assessment whose results appear only in the medical record). CAPI interviews reduce the need to budget for data entry per se, but consideration still has to be given to data management over the course of an interviewing project.

Once these demand characteristics have been determined, one can begin the task of actually selecting an interview:

1. *Review the available instruments and make a shortlist*. It may seem surprising that we place a review of available measures so late in the process. There are two reasons for doing this. First, the choice of measure should be dependent on the nature of the application, not the other way around, so until the application

has been well defined, the issue of instrumentation is moot. Second, once one has answered questions 1 to 6, a brief review of instruments may indicate that only one is even remotely suitable. To put it another way, it is more efficient to decide which interview to use relatively late in the process, because one may be able to save a lot of time that would otherwise have been spent in considering instruments that cannot meet the needs of the study. If there seem to be several possibilities at hand, one has at least reduced the number of instruments that need to be considered to a shortlist for further evaluation.

2. *Get copies of the instruments on the shortlist and conduct a detailed evaluation*. Unfortunately, there is absolutely no substitute for getting copies of the instruments still left on the shortlist and reviewing them in detail. The manifold differences between instruments make it impossible to provide more than a flavor of what an interview is like in a review chapter such as this. It is worth remembering that you will be asking the interview developers to send several hundred pages of schedules, glossaries, instruction manuals, and the like, and that these will need to be paid for. At this stage, it should be possible to make a final choice, but if there are still questions that have not been answered in all these materials, a telephone call to someone in the relevant interview development group can be very helpful. If the “homework” outlined above has been done, it is also likely to be well received.
3. *Plan training well ahead of time*. It is not unknown for an interview developer to receive a request like the following: “Hello, I put the … in a grant proposal, and the funding has just come through. I need you to train my interviewers next month.” Interview developers have busy research and clinical lives, and they cannot provide training programs at a moment’s notice. The time to be setting a hopeful date for training is *before the grant proposal is submitted*, not after it has been reviewed and funded.

FUTURE DIRECTIONS

A great deal of work has gone into producing the interviews we have today, and there is little sign that recent efforts to further “improve” such measures have had much effect on their reliability. Of course, as we learn more about psychopathology we will need to modify our measures’ content to reflect what we need to measure, but the basic principles used to design new or revised modules will not change in the foreseeable future (and will work just as well or poorly as they do today). What is needed now is to extend the range of structured assessments down to younger ages. There is astonishingly little research on preschool psychopathology, for instance, and it was only in 2000 that the first structured parent-report diagnostic interview specifically designed for use with this age group became available. It remains to be seen how information from the child and caretakers other than parents can usefully be integrated into diagnostic assessments, but work has begun in this area. Newer “self-

report" assessments of the mental status of the child that do not tie themselves rigidly to current diagnostic criteria show great promise for the future. For instance, with the MacArthur Story-Stem Battery (99–101) the interviewer uses toys to act out the beginnings of stories which the child is then asked to complete. The videotapes of these interactions are then scored to provide indices of a variety of internal states. The Berkeley Puppet Interview (102) employs two puppets to express two moods/states, and the child indicates the puppet most like him- or herself, thereby providing self-report assessments of perceived academic functioning, social relationships, depression, anxiety, and aggression/hostility. Some simpler "questionnaires with pictures" have also shown promise with preschoolers in relation to the assessment of depression and anxiety (103,104). Observational assessments, such as the Disruptive Behaviors Diagnostic Observational Schedule (DB-DOS), a structured observational measure to identify clinically significant disruptive behaviors in preschoolers (105), will also likely play a role in the diagnosis of preschool psychiatric symptoms and impairment in the future.

Now that many diagnostic measures are available, it is likely that they will move progressively into ordinary clinical practice. It seems strange that the unstructured clinical interview has been almost entirely supplanted for research purposes because of its well-documented inadequacies as a diagnostic procedure, but continues to be the main assessment tool in clinical practice, where good phenomenologic assessment is surely of the greatest importance. All clinicians dealing with psychopathology can benefit from training on an interviewer-based structured interview (particularly one of the glossary-based interviews), and it is to be hoped that such training will soon become part of all training programs for psychiatric clinicians. However, it must be admitted that the time to conduct a full psychiatric assessment is not always available, and when that is the case it would be helpful to have shorter interviews available to serve as screening tools. Here, a good start has been made with the DISC predictive scales (106), which have been shown to have good screening properties in relation to DSM-IIIR diagnoses. The idea here is not to force slavish dependence on any particular structured interview on clinicians, but to use the strengths of standardized interviews to underpin their explorations of the nature and meaning of psychopathology. Our understanding of psychopathology and its measurement has have come a long way, and it is time to bring the benefits of what are still typically regarded as being research assessment methods to all of our patients and clients.

CHAPTER 4.7 ■ DIAGNOSTIC CLASSIFICATION

FRED R. VOLKMAR, DENIS G. SUKHODOLSKY, MARY SCHWAB-STONE, AND MICHAEL B. FIRST

PRINCIPLES OF CLASSIFICATION

The ability and the urge to classify are unique aspects of human experience. They provide us with the capacity to observe, to order our observations, and to formulate general principles and hypotheses. Classification enables us to make use of information for purposes of communication, prediction, and explanation. At the present time in child and adolescent psychiatry, classification systems have their greatest role in facilitating communication for both clinical and research purposes; their role in prediction is somewhat more limited, and their explanatory value is often quite limited although the process of being assigned a diagnostic label may itself be associated with some sense of relief on the part of the patient or the patient's parents (1). Sometimes this reflects the misconception that having a label implies having an explanation (2). Like all human constructions, classification schemes can be abused or ill-used (3). This chapter provides an overview of classification in child and adolescent psychiatry and an overview of the current official systems, that is, the 10th edition of the *International Classification of Diseases* (ICD-10) (4) and the 5th edition of the *Diagnostic and Statistical Manual Mental Disorders* (DSM-5) (5). (Definitions for each disorder are discussed in detail in the respective chapters.)

Various authors (2,6–11) discuss criteria for psychiatric classification systems. There is no single "right" way to classify disorders in childhood. Classification systems vary, depending on the purpose of classification and what is being classified. As described later, "official" diagnostic systems have tended to adopt, on the whole, a categorical approach, but a dimensional approach would be equally as applicable, if perhaps less useful for clinical purposes.

The goals of classification include facilitating communication among professionals, providing information about given disorders that is relevant to treatment or to prevention, and providing information useful for research aimed at understanding the pathogenesis of disorders. To achieve these goals, classification schemes must be readily and reliably used by clinicians and researchers; hence the need for systems that are readily comprehensible. The disorders should be described, so they can be differentiated from one another. Disorders should differ in important ways, such as associated features and course. The classification system must be applicable over the range of development and must be comprehensive and logically consistent (12). A classification of disorders implies that some clinically significant patterns of symptoms, behaviors, and signs are observed and comprise a source of significant distress or impairment (5). Deviant behavior itself does not necessarily

constitute a disorder unless it is a manifestation of dysfunction within the individual person (e.g., conflicts over political beliefs do not constitute a mental disorder). Although it is often assumed that mental disorders must have a biologic basis, this need not be the case; for example, maladaptive, enduring personality patterns can readily be classified as disorders (13).

Development of a general classification system for psychiatric disorders inevitably involves various tradeoffs. General classification systems must cover the entire range of disorders in a logically consistent fashion; classification systems developed for a highly specific purpose or setting do not share this concern. The need for reasonable parsimony must be balanced with the need for adequate coverage (1,9). The needs for a clinically relevant system differ somewhat from those for a research system; for example, highly detailed criteria may be useful for research purposes but are cumbersome in clinical practice. Different diagnostic systems address these issues in different ways. Thus, the DSM-IV (5) was intended to be useful for *both* clinical work and research, whereas the ICD-10 (4) system provides *separate* clinical and research descriptions.

ISSUES IN CLASSIFICATION

Developmental Aspects

Developmental considerations assume major importance in the provision of a classification scheme for children and adolescents, and, indeed, for adults as well (14). Some disorders such as autism have their origin in a specific developmental period, whereas others are frequently associated with developmental problems, for example, Tourette syndrome may be associated with attentional or learning difficulties. At other times, the child's overall level of development may have a major impact on the ways in which various disorders can be expressed (the child with intellectual disability who also exhibits conduct problems). Classification systems must be able to encompass such issues without simultaneously making the disorder so developmentally specific that the utility of the category is compromised.

The developmental approach to classification is used whenever disorders are viewed in the context of the unfolding of basic developmental processes. The use of standard, developmentally based assessment instruments such as tests of intelligence or communication skills exemplifies this approach. In contrast, many categorical and dimensional classification systems rely on assessment of deviant behavior. The use of such an approach is often complicated because issues of how deviant behavior is to be evaluated and how instruments are to be "normed" become quite important, and reliability among examiners can be low. Both the ICD-10 and the DSM-5 systems include some categories in which the definition is fundamentally developmental (intellectual disabiltiy, articulation disorders), whereas in others the "deviant" nature

of the disorder predominates (autism, schizophrenia of childhood onset).

Role of Theory

Theoretical models of psychological disturbance have developed from diverse historical traditions and have considerable value for the individual clinician in understanding and treating children with emotional and behavioral problems. For example, Anna Freud (15) proposed a developmental profile based on and applicable to psychoanalytic assessment of children. More phenomenologically based classification systems can be traced to Kraeplin's delineation of schizophrenia and bipolar disorder (16). In the early "official" classifications (e.g., DSM-I and DSM-II), theoretical concerns were reflected in terms such as "schizophrenic reaction of childhood" or "obsessional neurosis." Classification schemes that are driven by theory are limited because, by their nature, they are based on a set of assumptions and hypotheses not usually generally shared and may give rise to different terms used to describe the same clinical phenomena; for example, a learning theorist may invoke principles of conditioning to explain a child's phobia, whereas a psychoanalytically oriented clinician may be more concerned with the child's level of psychosexual organization. Particularly following the work on development of research diagnostic criteria (17), starting with DSM-III in 1980, the phenomenologic approach to classification has predominated in the various "official" diagnostic systems. The more robust diagnostic concepts have typically emerged from clinical experience rather than from theory (18). In some instances, a theory has been invoked to account for a given set of phenomena, but it is the set of phenomena rather than the theory that has endured. For example, Langdon Down provided a complex theoretical explanation for children with the condition now known as Down syndrome. His theory, based on obsolete racial stereotypes (mongolism), was incorrect, but his observation of some element of commonality among a large group of children with intellectual disability has proved enduring.

For clinicians with pronounced theoretical views, the more phenomenon-based approach can be a source of frustration. It is sometimes incorrectly assumed that in such an approach matters as history, course, and outcome, and, for that matter, etiology and theory are irrelevant to classification. Information on course and outcome may provide important data relative to external validation of diagnostic categories, and information on the development of the disorder may be highly relevant to differential diagnosis regardless of how similar, at one point, two different disorders may appear to be. For example, the syndrome of childhood disintegrative disorder clearly appears to resemble autistic disorder once it is established; however, patterns of early development and outcome differ in these conditions (19). Theoretical views of conditions and mechanisms remain highly relevant for both clinical work and research because they are more likely to generate

truly testable hypotheses.

Etiology and Classification

It is often assumed that classification systems are developed to approximate some ideal diagnostic system in which the etiology could be directly related to clinical condition. This is not, in fact, the case, in that no single ideal system is waiting to be discovered and that etiology need not be included in classification systems (12). Similarly, classification need not reflect a “disease” model (12). Different etiologic factors may result in rather similar clinical presentations and the same etiologic factor may be associated with a range of quite different clinical presentations. Aspects of intervention may be more directly related to the clinical presentation than to the cause. Remedial services for children with intellectual disability are, for example, much more likely to be oriented around aspects of developmental level than around the precise etiologic origin of the intellectual disability. With a few exceptions (reactive attachment or posttraumatic stress disorders), etiologic factors are not generally included in official diagnostic systems.

Contextual Factors

In certain situations and populations, contextual variables such as family, school, or cultural setting pose major complications to diagnosis. The attentional problems of a child whose difficulties arise only as a result of an inappropriate school placement would not, for example, merit a diagnosis of attention-deficit disorder. Contextual variables are particularly problematic in disorders of infancy and early childhood in which the infant exerts effects on the parents, who, in turn, exert effects on the child; attributions of causality in such situations may be particularly difficult to make (20). A few of the traditional categorical disorders can be readily observed in infants and young children (e.g., autism), but generally clinical complaints in this age group are centered around problems that encompass the infant in the context of the family, the individual’s age or developmental level, or life situation. These issues are particularly relevant for diagnosis of disorders in infancy—an area that remains somewhat controversial so that, for example, a diagnosis of autism can often be made in very young children (21), although in some cases not all features are exhibited until around age 3 (22). Although research on disorders of infancy is limited (23), it is clear that infants exhibit a tremendous ability to react, even over relatively short periods, to their environment, and change, rather than stability, is often the rule (24). Clinical problems often relate more to issues of *goodness of fit* between parents and the infant than to a disorder in the infant (25). As children become slightly older, traditional diagnostic groupings become more readily applicable (26). Issues of developmental level also become important in specifying inclusion and exclusion

criteria for diagnostic categories; for example, a diagnosis of Pica may be appropriate for a 12-year-old child with profound intellectual disability but is less appropriate for a normally developing 10-month-old infant. These are important issues for DSM-5 and for the new ICD-11.

Cultural differences may also affect diagnostic concepts and practice (27). Clearly, certain sociocultural factors are associated with certain types of problems (e.g., economic disadvantage is associated with conduct and attentional problems), but the meanings of such relationships often remain unclear (28).

What Is Classified?

It is particularly important that clinicians and researchers alike bear in mind that disorders, rather than children, are classified. This is a source of considerable confusion. Concerns have been raised about the possible effects of labeling children (3), and to some extent these concerns are valid. It is, of course, also the case that having an adequate label for a child's disorder may be helpful, for example, in securing needed services. Thus, a diagnosis of intellectual disability or specific learning disorder may be associated with social stigma or other untoward effects, or it may be associated with more realistic expectations on the part of parents and teachers and provision of potentially more appropriate services. These tensions are also exemplified in the debate between those who advocate broad and encompassing definitions (to maximize clinical and educational service provision) and those who advocate narrow definitions (by defining more homogenous groups of research subjects).

Similar debates arise about aspects of social stigma related to mental illness and behavioral and developmental problems. In this regard, it is always important to refer to the child's disorder, *not to the child as the disorder* (e.g., "child with a diagnosis of schizophrenia" rather than "schizophrenic child"). The term *diagnosis* refers both to the notion of assigning a label to a given problem and to the act of evaluation. In important respects, it is the diagnostic process (29) that is the most important of the two. Although diagnostic labels have considerable value, they do not provide information specifically about the individual person, who is unique and uniquely related to intervention.

VALIDATION AND STATISTICAL ISSUES

As official classification systems have become more complex and sophisticated, issues of reliability and validity have assumed increasing importance. For example, both the DSM-IV and the ICD-10 used results of large national or international field trials in providing definitions of disorders. Categorical and dimensional approaches to classification share certain statistical concerns (6).

Validity

Validity is the extent to which a classification system does what it purports to do in terms of facilitating communication, intervention, and research. Various types of validity have been identified, for example, *face validity* (a judgment about whether the description of a category appears to represent the diagnostic construct reasonably), *predictive validity* (whether some aspect of subsequent course or response to treatment is predicted), and *construct validity* (whether the category has meaning in terms of what it purports to assess). Generally, such concepts are most useful in measuring the validity of psychometric assessment instruments; their applicability to classification systems is somewhat different. In general, childhood psychiatric disorders have face validity but not necessarily predictive or construct validity (11). The validity of a given diagnostic category can be established on the basis of its association with various features other than those incorporated in the definition (response to treatment, natural history in the absence of treatment, family pattern, biologic correlates, and developmental correlates such as age at onset and intelligence quotient).

The sensitivity and specificity of a given categorical diagnostic instrument can be assessed relative to the true presence or absence of a specific disorder. However, a general problem for both categorical and dimensional classification systems is the nature of the standard against which a given category or criteria set is to be judged. Given the usual absence of an unequivocal diagnostic marker for the various conditions, clinical judgment is often used as the standard against which new instruments or definitions are assessed. The issues of “caseness” and diagnostic thresholds are particularly important in the derivation and validation of diagnostic systems (30,31). These issues can be complex, for example, if impairment is a necessary feature of a condition like Tourette’s disorder what is the best approach given the strong genetic component of the condition, that is, a father might have mild and nonimpairing tics but have a son who is quite disabled.

Reliability

In addition to validity, classification systems should exhibit *reliability;* that is, users in different locations seeing rather similar disorders should be able to agree on the applicability of a specific category or criterion (32). Various kinds of reliability have been identified: interrater, test–retest, and internal consistency. If a given category is not used reliably, it has little value for purposes of communication. Some disorders, almost by definition, have limited test–retest reliability over a relatively short time period (adjustment disorder), whereas other highly stable disorders tend to have better test–retest reliability (profound intellectual disability). Sources of unreliability in psychiatric diagnosis include differences in the kinds of information

clinicians collect, theoretical biases in the clinician, and differences in internalized diagnostic thresholds, as well as, of course, the true differences that persons with disorders will exhibit at various points over the course of their condition.

High reliability does not guarantee validity. It is possible for a disorder to be reliably defined but have little or no validity. Conversely, a disorder may have validity, but criteria and diagnostic instruments designed to detect its presence may have little or no reliability. In providing diagnostic criteria and descriptions, there is often a tradeoff between the level of detail of a definition and its reliability. What appear to be relatively minor changes in the wording of a criterion can produce major changes in the way in which a diagnosis or diagnostic criterion is applied.

Statistical Analyses

Various *statistical techniques* have been applied to data derived from assessment methods (8,33,34). These techniques are theoretically of great interest in that they can provide more rational and empirical approaches to the derivation of diagnostic schemes. The fundamental assumption of such techniques is that the variables of interest lie along some dimension of function and dysfunction that all persons exhibit to some degree. For many types of problems, this assumption is probably justified, such as relative to anxiety or depression. However, the usefulness of such techniques is limited in important ways (12). In the first place, these methods are highly dependent on both the sample and the type of data entered in the analysis. For example, *factor analysis* of an instrument designed to detect conduct problems would not likely produce a factor related to eating disturbance. Similarly, cluster analysis of even a very large normative sample would not likely produce a cluster that corresponded to autism, given the low base rate of this disorder in the population. For rare disorders, other statistical approaches may be useful. Other relevant statistical procedures include *signal detection analysis* (35), which can be used to establish which symptoms and symptom combinations are more strongly related to a particular diagnosis. Similarly, *latent trait analysis* and *latent class analysis* (36,37) provide other approaches.

MODELS OF CLASSIFICATION

Werry (1) delineated three general approaches to classification of disorders: categorical, dimensional, and ideographic. The *categorical approach,* sometimes referred to as the medical model of classification, views disorders as either present or absent (the patient does or does not have appendicitis). This approach assumes that patients exhibiting a given disorder display certain similarities, that these similarities outweigh differences, and that this knowledge has certain implications for understanding pathophysiology, course, treatment, and so on. Unlike the

categorical approach, which views disorders as dichotomous, the *dimensional approach* to classification relies on assessment of dimensions of function or dysfunction by reducing phenomena to various dimensions along which a child can be placed. Various sources of data can be used for this approach, such as behavioral ratings, parental reports, sums of yes–no criteria, developmentally based test scores, and the like. Although the dimensional approach is more commonly used in nonmedical settings, many medical phenomena also exhibit continuous (dimensional) characteristics (stature, blood pressure). For some purposes, categorical diagnoses (levels of intellectual disability) are derived from what is essentially a continuous variable, whereas some dimensional assessment instruments can similarly be used to generate categorical diagnoses. *Ideographic classifications* reject simple labels and focus on the total context of the individual person; this approach may be theory-driven (by psychoanalytic or behavioral theories) or may be used eclectically. Ideographic approaches are commonly used in clinical work; that is, the child or adolescent is viewed in the totality of life circumstance, and various disorders, problems, and psychosocial situations may be viewed as worthy of notation and treatment.

Categorical Approaches

The most widely used "official" systems are those developed by the World Health Organization (WHO) (ICD-10) (4) and the American Psychiatric Association (DSM-5) (5). There systems have their historical origins in medicine in the 19th and 20th centuries as advances in diagnosis and public health concerns necessitated more systematic approaches to record-keeping (Table 4.7.1). During the 19th century, many advances in the taxonomy of adult psychiatric disorders were made, and this led Kraepelin to attempt a comprehensive classification system (38). By the mid-20th century, certain psychiatric disorders were generally recognized. The second edition of the DSM (DSM-II) (39) includes only a handful of diagnostic categories specific to children: intellectual disability, childhood schizophrenia, adjustment, and other "reactions" (hyperkinetic, withdrawing, overanxious, runaway, unsocialized aggressive, group delinquent, and "other"). By the time the DSM-III appeared (40), the number of disorders first evidenced in infancy, childhood, or adolescence had increased more than fourfold to include the following major classes of disorder, each of which included some specific diagnostic categories: intellectual disability, specific developmental disorders, attention-deficit disorder, conduct disturbance, eating disorders, stereotyped movement disorders, pervasive developmental disorders, other disorders with physical manifestations, and other disorders of infancy, childhood, or adolescence (16). Similar, although not precisely corresponding, changes occurred in the revision of the ICD 10 (4). In the DSM-III, for example, disorders generally specific to childhood were grouped together, and

there were many more DSM-III subcategories (40). The DSM-III and its successor, the DSM-III-R (41), differ from the ICD-9 in terms of their greater diagnostic reliance on explicit (if not always truly operationalized) diagnostic criteria (42,43). Both the DSM and the ICD incorporate multiaxial framework, although the specific systems adopted differ from each other in some respects. Both systems were hierarchically organized, although the DSM-III and the DSM-III-R encourage multiple diagnoses. Changes in the DSM-III-R and DSM-IV are generally less dramatic than in the DSM-III (44). Work on the DSM-IV began in 1988 (45), stimulated, in part, the desirability of harmonizing DSM-IV with ICD-10, which was also undergoing revision at that time. As part of the process of producing the DSM-IV, steps were undertaken to ensure that changes made were based on solid empirical data and thorough documentation (45). This task was somewhat facilitated because it was clear that the DSM-III and III-R had stimulated considerable research of relevance to the DSM-IV (46). Other issues for the DSM-IV relate to clinical utility and compatibility with ICD-10. As part of the revision process, extensive literature reviews were conducted, datasets were aggregated and analyzed or reanalyzed, and working groups of experts convened to evaluate the available data and, in some cases, to generate new data. For the child disorders section, field trials were conducted for disruptive behavior disorders (47) and for autism and related conditions (48).

TABLE 4.7.1

Landmarks in The Development of Psychiatric Taxonomies[a]

Kraepelin (1883): Proposal for a comprehensive classification system
ICD-6 (1948): Psychiatric disorders included
DSM-I (1952): First US official classification system
Group for the Advancement of Psychiatry (1966): Diagnostic system for children
DSM-II (1968): Some child disorders, emphasis on theory and Meyer's concept of reaction types
DSM-III (1980): Fourfold increase in child psychiatric disorders, greater diagnostic precision, multiaxial
DSM-III-R (1987): Refinements in criteria, categories
ICD-10 (1992): Separation of research diagnostic criteria from clinical descriptions
DSM-IV (1994): More emphasis on data based modifications in categories and criteria
DSM-IV-TR (2000): Generally minor revisions in text (not criteria)
DSM-5
(2013): Major revision, drops subthreshold concept
(2002): Research agenda and white papers
(2012): Anticipated publication date

[a]DSM, Diagnostic and Statistical Manual of Mental Disorders; ICD, International Classification of Diseases.

The *International Classification of Causes of Death* was adopted by the International Statistical Institute in 1893 (49). By the 1960s, the ICD had been revised six times, and the deficiencies of the ICD-7 for psychiatric disorders (10) were particularly clear. Many changes were made in the eighth edition of the ICD in 1968. Even when this edition was adopted, however, it was clear that further

revision would be needed, and a process was instituted for further revision. An important part of this work was the development of a multiaxial classification system for child disorders (10).

The ICD-9 was published in 1977, and work on its revision began shortly thereafter (50–52). As part of the extensive revision process, the number of categories increased substantially (53), and a decision was made to have several versions of the system—one for primary health care providers, another for specialty-based researchers, and one for psychiatric practitioners. The ICD-10 had good clinical utility and good, although variable, reliability (the latter being less optimal for disorders with more subtle symptoms such as personality disorders) (51,54,55); it also included a handful of mixed categories (e.g., depressive conduct disorder) for the more frequent co-occuring disorders in childhood (56).

DSM-5

DSM-5 (5) was published in 2013 and marked the first major DSM revision in nearly two decades (57,58). Prior to starting formal work on DSM-5, a research planning effort was initiated with the goal of stimulating research in advance of starting the revision process. The first phase of the effort produced a series of white papers, which were published in 2002 in *A research agenda for DSM-V* (59). One of the white papers (60) reviewed advances in the developmental sciences and proposed a research agenda for the next decade focusing on six areas of research that have the potential to refine the classification of developmental psychopathology. These included (1) developmental neuroscience and genetics, such as studies in animals to determine associations between maternal behavior and hypothalamic–pituitary–adrenal axis regulation; (2) prevention, including studies of early intervention for children and adolescents; (3) improved diagnostic classification of disorders of infancy and early childhood; (4) improvements in the multiaxial system; (5) approaches to psychiatric assessment: integration of information from different assessment approaches; and (6) developmental epidemiology, entailing large-scale population-based samples of children studied from birth, or even earlier, through adulthood.

The final version of DSM-5 was released in May of 2013 and sought to address both the challenges in diagnosing mental disease and the advances that have been made in the 20 years since the last version (58,59,61). Significant changes to the overall structure, including the elimination of the section for Disorders Usually First Diagnosed in Infancy, Childhood, or Adolescence and the decision to rely, as much as possible (59), on standardized diagnostic instruments and neuropsychiatric findings for the source of defining the included disorders, were made. The overall approach to childhood-onset disorders, that is, in general (apart from those disorders with strong developmental components), to move descriptions to overarching

categories, for example, anxiety disorders, rather than have a section of the manual focused on childhood-onset conditions. The NOS categories were replaced with "Other Specified Disorder" and "Unspecified Disorder" categories.

Also, it was noteworthy that the previous multiaxial system was eliminated with a list of all disorders on a single axis along with the potential for listing psychosocial and contextual features and the potential for using the WHO disability assessment schedule (rather than the previous axis V).

At the level of disorders included decisions were made to drop a number of categories, for example, Asperger's syndrome. Newly recognized conditions were relevant to social communication disorder (a communication disorder with a strong social component). Gender identity disorder was renamed as gender dysphoria. A new category of disruptive mood dysregulation disorder was included specifically for children and adolescents with chronic irritability punctuated by frequent temper outbursts, which is intended to be used instead of juvenile bipolar disorder. The name for mental retardation was replaced with intellectual disability. The DSM-IV categories of phonologic disorder and stuttering were renamed speech–sound disorder and childhood-onset fluency disorder, respectively. Similarly, a new category of motor disorder includes tic disorder, coordination, and stereotyped mood disorders. For some disorders, for example, enuresis, no major changes were made from the DSM-IV approach. Clarifications were made in some cases, for example, for Pica, to indicate that the behavior could be observed at any age. Newly recognized diagnosis included binge eating disorder and changes were made in criteria for both bulimia nervosa and anorexia nervosa. The rarely used DSM-IV category of feeding disorder was reconceptualized as avoidant/restrictive food intake disorder with a new set of criteria. Changes were made in the DSM-IV approach to oppositional and conduct disorder.

Criticisms of the new approaches included the inclusion of new disorders with little or no empirical support (e.g., social communication disorder) and, low inter-rater reliability (e.g., disruptive mood dysregulation disorder). For childhood-onset disorders, concern was raised regarding changes in the autism section—the name change for the overall category (from pervasive developmental disorders) to autism spectrum disorder (ASD) was applauded although a substantial body of work (62) suggests paradoxically that the definition for ASD is much more appropriate to more "classic" autism (as typified by Kanner's original cases). As a result, the final autistic disorder definition "grandfathered" in previous "well-established" diagnoses like Asperger's and PDD–NOS effectively maintaining the DSM-IV approach.

ICD-11

The 11th revision of the *International Classification of Diseases* (ICD-11) is currently being developed by the WHO and is expected to be approved by the World

Health Assembly in 2018 with implementation by WHO member countries in subsequent years. Given that the neuroscience and genetics evidence that has accumulated over the past 20 years does not support major changes for individual conditions or provide definitive support for specific structure, the primary focus of the revision of the Mental and Behavioural Disorders chapter is to improve the clinical utility of the classification. A significant change in ICD-11 as compared to ICD-10 is the use of a standardized template for the presentation of the clinical descriptions and diagnostic guidelines (63). At present, it appears that, on balance, ICD-11 will be more similar to DSM-5 than different but important details remain to be decided. A draft version of ICD-11 clinical descriptions and diagnostic guidelines is available (63). Moreover, extensive Internet-based case vignette studies and clinic-based diagnostic agreement studies are underway (64).

Dimensional Approaches

In contrast to the more clinically oriented (categorical) approach, multivariate (dimensional) approaches to diagnosis offer several potential advantages in that various behaviors and dimensions of behavior are assessed, rather than single, presumably pathognomonic, features (8,33,34). Similarly, the dimensional approach can encompass symptom coding in other than a dichotomous fashion; for example, “never,” “sometimes,” and “always” could be coded, rather than simply presence or absence, to rate specific diagnostic features. Various rating scales, checklists, and so forth can be used for multivariate classification schemes based on self, parent, or teacher report or on direct observation; many such instruments are described in subsequent chapters. As noted previously, various statistical techniques such as factor and cluster analysis may be used to derive relevant clinician patterns or profiles. These patterns may, in turn, be used to derive categorical diagnoses. Given the inherent problems in sample selection and instrument development, issues of replication are particularly important (12).

Early work focused on examination of patterns of relationships (correlations) between variables to derive syndrome groupings (65). A large series of case records was studied, and the presence or absence of specific behaviors was noted in each case. Clusters of deviant behavior were noted, and broad patterns of disturbance (socialized delinquent, overinhibited, unsocialized aggressive) were identified. Subsequently, more sophisticated methods have been applied to a range of children using a variety of assessment instruments (33). Studies done using this approach generally identify several factors with relative consistency; factors identified have included conduct disturbance, overactivity, and emotional disturbance (12,66). Not surprisingly, the stability of more narrowly defined factors is less robust. Similarly, as would be expected, such techniques have limited usefulness in detecting children with disorders of very low prevalence.

Reliability of dimensions derived from multivariate studies has been assessed and is generally satisfactory (8). Stability of dimensions or profiles is somewhat more complex to assess, in that some change is, of course, expected, but short-term stability appears to be within acceptable limits (8). The use of dimensional assessment instruments clearly avoids certain of the pitfalls inherent in the categorical approach, for example, in terms of the loss of information inherent in the application of dichotomous categories, in increasing reliability, and in issues of "caseness." These issues are relevant to medicine in general and not just to psychiatry.

For some purposes, dimensional assessment instruments are particularly valuable. For such assessments to be clinically useful, their validity must be demonstrated, for example, in terms of some associated features, such as familial pattern or course. The assumption that characteristics have the same meaning throughout their distribution is often questionable (e.g., severe intellectual disability differs in a host of ways from normal intelligence) (55). Certain disorders clearly do *not* shade off into normality. At the same time, it is important to note effects of biologic development on syndrome expression (67).

RELATIONSHIP OF CATEGORICAL AND DIMENSIONAL APPROACHES

There are major areas of agreement between both the categorical and dimensional approaches; this is particularly true for the more common disorders. Analysis of data from dimensional assessment instruments has proved useful in the development of categorical systems, for example, in supporting division of conduct disorder into various types. Probably the greatest drawback to the use of such assessments in clinical practice arises from the difficulty in using such instruments in a simple way for purposes of communication; for clinical purposes, it is more helpful to know that a child has attention-deficit hyperactivity disorder and learning problems than to know his or her factor or profile scores on a dimensional assessment instrument. Dimensional and categorical approaches need not be used in mutually exclusive ways; the multiaxial classification used in the DSM-III-R, for example, employs both approaches in that although disorders are categorically defined, assessments of severity of psychosocial stressors and global assessment of functioning are dimensional.

IDEOGRAPHIC APPROACHES

Ideographic approaches (1) to diagnosis are common in clinical practice. In the broader sense of diagnosis (as diagnostic process) (29), most clinicians target

certain problems or issues for intervention that relate only in part to categorical or even dimensional diagnosis. In some ways, such approaches are more practical in certain situations (family therapy), although again they can be used in conjunction with categorical approaches. They are less useful for certain purposes (in considering pharmacologic intervention) (1). Past the level of the individual cases, the utility of ideographic approaches is limited. Such approaches make it very difficult to communicate information for clinical and research purposes in a concise and readily understood fashion. Chapter 4.1 suggests efficient ways of incorporating the various classification systems into a meaningful understanding of the patient, in order to institute a balanced and informed treatment plan.

RDoC

The Research Domain Criteria (RDoC) project is a framework for conducting research that has been launched by the NIMH in order to gather empirical data to ultimately develop a new classification of psychopathology based on the dimensions of neurobiology and behavior that cut across traditional categories of mental disorders (68). In contrast to the DSM and ICD classification systems which are intended for clinical use, the RDoC approach is not a classification system per se but is intended for researchers to provide a working model to stimulate research on the core dimensions (or constructs) of psychopathology. First, in 2009, an NIMH workgroup devised a proposal for a new system and outlined five major domains of functioning such as cognition and emotions, and units of analysis ranging from genes to neural circuits to behavior. Then, five groups of experts in basic and behavioral sciences representing each of the domains were convened for a series of workshops and asked to determine and define specific dimensions to be included in each domain. In order to be included, the domains (e.g., "fear") had to reflect validated behavioral functions and show evidence for a neural circuit or system responsible for implementing this function.

The ensuing RDoC constructs are organized in a two-dimensional matrix of five domains that include constituent constructs in the rows and seven units of analysis as the columns (69). The *units of analysis* include genes, molecules, cells, circuits, physiology, behavior, and self-report, reflecting a range of methodologic approaches from genetics to psychology. The first three levels of analysis pertain to neurobiologic mechanism of circuitry essential to each construct. In turn, neural circuits is a central unit that can be studied with neuroimaging methods such as functional magnetic resonance imaging or indices of circuit activity such as fear-potentiated startle. Physiology refers to variables such as event-related potentials or heart rate variability that can be validated as indirect measures of neural circuits. Measures of observable behavior and performance on laboratory task are grouped under the unit of analysis termed "behavior." Lastly, self-report category is reserved

for interviews, rating scales, and other psychometric instruments of various aspects of the construct of interest that represent signs and symptoms of psychopathology. This emphasis on the multifaceted characterization of constructs is part of the RDoC's aim to incorporate methods of genetics, neuroscience, and cognitive science into the future classification scheme of mental disorders.

The RDoC constructs are grouped into domains of functioning that reflect key aspects of emotion, motivation, cognition, social behavior, and regulatory systems (70). The first domain, *negative valence systems,* includes constructs defined by responses to acute threat ("fear"), potential threat ("anxiety"), sustained threat, loss, and frustration. The second domain, *positive valence system,* contains constructs defined by reward learning and habit formation. For example, approach motivation construct encompasses goal pursuit behaviors subserved by the mesolimbic dopamine system. A dysfunction of this system can lead to abnormally low (e.g., avolition) or high (e.g., addition) goal-directed behaviors. Another construct within this domain called "habit" is viewed as a manifestation of reinforcement learning where repetitive motor or cognitive behaviors occur and manifest without serving an adaptive goal. The *cognitive systems domain* encompasses six broad constructs: attention, perception, declarative memory, language, cognitive control, and working memory. The *social processes domain* includes constructs that bridge social behavior with neural circuits of attachment, social dominance and perception, and understanding of self and others. For example, facial communication may include receptive aspects of facial affect recognition and productive aspects of eye contact and gaze following. The neural underpinnings of these behaviors have been studied with an array of neuroimaging and electrophysiologic methods in order to established biomarkers of psychiatric disorders such as ASD and schizophrenia. The fifth domain includes *arousal and regulatory systems* that subserve many of the other domains and are central in sleep and wakefulness.

The RDoC framework is based on three core assumptions: (1) mental illnesses are presumed to be disorders of brain circuits, (2) neuroscience tools can identify the pathophysiology, and (3) the discovery of biosignatures will supplement diagnoses based on clinical signs and symptoms and direct assessment and treatment of mental illness (71). These assumptions have been critiqued for overly biologizing mental illness and their relative lack of emphasis on developmental and environmental influences on mental health and illness, as these variables are missing in the RDoC matrix (72). However, since its inception, the RDoC approach has stimulated an increasing body of research on developing and validating the proposed constructs along the lines that are outlined in the RDoC matrix. In addition, RDoC offers a new perspective to study co-occurring disorders. For example, autism commonly co-occurs with anxiety, but when using symptom-based criteria, it is hard to know whether anxiety is a true comorbidity or a feature of autism. However, measures that have been validated to test relevant functions within anxiety/fear circuitry and social

brain networks can provide an alternative way for characterizing anxiety in autism (73). Treatment studies can also benefit from the RDoC approach by focusing on brain/behavior associations as the primary outcome variables. For example, randomized control studies can test whether reduction of behavior (e.g., aggression) is associated with changes in socioemotional circuitry (e.g., connectivity of the amygdala with ventromedial prefrontal cortex), thus testing the constructs of the RDoC matrix (e.g., frustrative nonreward) (74).

SUMMARY

Classification in child and adolescent psychiatry has multiple meanings and functions. Complications for classification of child and adolescent disorders are myriad: The child is often not the person complaining; different kinds of data may be used in making a diagnosis; developmental factors may have a major impact on the expression of disorders; and certain features (e.g., beliefs in fantasy figures) are normative at certain ages but not at others. Additional complications are posed by the unintended, but no less real, uses to which diagnostic concepts are put, such as their inclusion in legislation and their use as mandates for services in educational programs or for purposes of insurance reimbursement for services. Different kinds and levels of classification are needed for different purposes.

The past 20 years witnessed tremendous advances in the area of diagnosis and classification of child and adolescent psychopathology. These advances are particularly welcome because work in this area had lagged behind that in the adult psychiatric disorders. Various approaches to classification have been employed; each has its advantages and limitations. Issues of reliability and validity remain to be addressed for many categories and classification systems; the attempt to address these issues through examining empirical data rather than theorizing is perhaps the greatest accomplishment of these efforts.

Tensions between clinical and research utility will continue to exist. As classification systems become more complex, they are less readily used; conversely, simplistic systems fail to capture important aspects of clinical experience. The likely ability, over the next decade, to identify more clearly the role of genetic factors for at least a few conditions and the growing sophistication of statistical approaches to aspects of classification and diagnosis represent important areas for future work.

A classification scheme is best used by persons with considerable training who take the task of diagnosis (in its broadest sense) seriously. Although categorical systems increasingly use diagnostic criteria, these are often not truly operationalized, although they are often abstracted and reified for specific purposes (development of interview schedules administered by lay interviewers, or the use of simple frequency counts or symptom duration that obscures the more central aspects of the underlying clinical construct). Although the various “official” systems present areas of

disagreement, the areas of agreement are even more noteworthy. Certain issues, such as classification of combination categories versus the use of multiple diagnoses, remain to be resolved. Specific issues arise with respect to inclusionary and exclusionary rules and aspects of comorbidity. Although much has been accomplished, considerable work remains to be done.

SECTION V

SPECIFIC DISORDERS AND SYNDROMES

5.1 ATTENTION AND DISRUPTIVE DISORDERS

CHAPTER 5.1.1 ■ ATTENTION-DEFICIT HYPERACTIVITY DISORDER

LACRAMIOARA SPETIE AND EUGENE L. ARNOLD

DEFINITION

Attention-deficit hyperactivity disorder (ADHD) is a syndrome of inattention, distractibility, restless overactivity, impulsiveness, and other deficits of executive function. It involves impairment of the ability to "plan your work and work your plan." DSM-5 diagnosis of ADHD requires either six of nine inattentive symptoms (e.g., carelessness about details, easy distraction, not listening when spoken to, easily losing focus, failure to complete tasks, avoiding tasks that require sustained attention, forgetfulness, and easily losing things) or six of nine hyperactive-impulsive symptoms (e.g., often fidgeting, squirming, or leaving seat when expected to remain in place, running, climbing or talking excessively, unable to be still or quiet for extended reasonable time, often having a hard time waiting their turn, often intruding or interrupting others) present for at least 6 months, dating from before age 12, not better explained by another disorder, and causing impairment in at least two settings academically, socially, or in daily living function. Six inattentive symptoms qualify for a diagnosis of inattentive presentation; six hyperactive/impulsive symptoms qualify as hyperactive/impulsive presentation; and six of each qualify as combined presentation. For patients age 17 and older, five symptoms from a list are sufficient.

It can be full expression (combined type—DSM-IV (1) or combined presentation —DSM-5, with six symptoms from each list of nine) (2) or partial expression (inattentive or hyperactive-impulsive types or presentations, with six symptoms from one of the lists). It is not necessary to have all the symptoms to qualify for the diagnosis. It is possible for two patients to meet diagnostic criteria with no symptoms in common and it is even possible to have the same presentation with only half the symptoms in common. This leads to wide variability in presenting problems and severity, which is further complicated by common associated symptoms such as irritability, boredom, and impaired social skills, and by psychiatric comorbid diagnoses.

There has been controversy in the literature as to whether the diagnosis of ADHD should be regarded as a category or as a dimension. Recent findings from genome-wide association studies question the basis of current classifications and the extent to which disorder categories reflect overlapping or distinct neuropathologic entities. The categorical view proposes that ADHD is qualitatively different from any variation of normal. The dimensional view proposes ADHD symptoms are on a continuum with variations on a spectrum of severity and only differ from normal in degree (3).

THE ATTENTION-DEFICIT HYPERACTIVITY DISORDER CONCEPT AND TERMINOLOGY

As early as the mid-19th century, the problems of inattentiveness and overactivity in children were recognized by Heinrich Hoffman (4) in the moralistic children's book *Slovenly Peter,* which featured the characters Fidgety Phil and Harry Who Looks in the Air. In the early 20th century, Still's disease was recognized as the behavioral sequelae of viral encephalitis. The behavioral constellation, particularly the overactivity and impulsiveness, were therefore considered "minimal brain damage," which morphed over time into "minimal brain dysfunction" as diagnosticians realized it was not possible to find evidence of actual brain damage in most cases (at least not with the technology available through the 1970s). Other descriptive terms used by the second half of the 20th century included hyperkinesis, hyperkinetic syndrome, hyperactivity, hyperactive-impulse disorder, psychoneurologic integration deficit, and pseudoneurosis.

The first diagnosis to describe children with symptoms of ADHD was the diagnosis of Hyperkinetic Impulse Disorder introduced by Laufer et al in 1957 (5a). In 1970 the second edition of the Diagnostic and statistical Manual (5b) identified the syndrome as "hyperkinetic reaction" based on the then-prevailing psychodynamic philosophy that mental disorders were always reactions to some stressor. The term "hyperkinetic disorder" (HD) is still used in the current International Code of Diseases (6). Recognizing that the cause of most mental disorders is more complex than a reaction to stress, the DSM-III (7) changed in 1980 to descriptive phenomenologic terms without causal implication. By that time the importance of inattentive symptoms had been recognized, leading to the appellation "attention deficit disorder," which could be diagnosed either without (ADD) or with hyperactivity (ADDH). The term ADD is still used by many to refer to the inattentive subpresentation, and is preserved in the names of such support/advocacy groups as Attention-Deficit Disorder Association (ADDA) (8) and Children and Adults with ADD (ChADD) (9). DSM-III-R (10) added overactivity back to the name of the disorder via the term "attention-deficit/hyperactivity disorder (ADHD)." This name was retained by DSM-IV although the symptom list changed somewhat, being expanded from 14 to 18 symptoms and being split into two lists of 9 each (Figure 5.1.1.1). The age requirement for symptom onset was changed to age 12 in DSM-5 (rather than age 7 in DSM-IV), but the name of the disorder was preserved as in DSM-III-R.

The ICD-10 criteria for HD (11) are more restrictive than the DSM-IV criteria in that all three symptom clusters of inattention, hyperactivity and impulsivity should be present and pervasive across settings and that the presence of anxiety or mood disorder is in itself an exclusion criterion. ICD 10 also includes the diagnosis of

hyperkinetic conduct disorder (HKD), which would be roughly the same as the DSM equivalent of ADHD combined presentation with comorbid conduct disorder.

EPIDEMIOLOGY

ADHD is one of the most common childhood-onset psychiatric disorders, affecting 5% to 12% of children worldwide. ADHD is a costly public health concern (12) since it can cause significant impairment in functioning that interferes with normal development and all areas of functioning in patients of all ages.

Epidemiologic studies of ADHD addressing issues of frequency, distribution, determinants, comorbidity, long-term outcome, and impact of treatment have been complicated by several problems. The first is integrating the different types of information from various sources required to make the diagnosis. A related problem is how to correct for the subjective nature of the information provided by the informants. The diagnosis could be easily overestimated if the information obtained does not include the level of impairment caused by the symptoms reported (13). Another problem is the difficulty integrating epidemiologic information obtained over time due to the ongoing refinement in the diagnostic criteria for ADHD. The current DSM-5 criteria allow the inclusion of more females, preschoolers, and adults presenting with significant impairment but who would have been otherwise excluded (14). The definition of ADHD may continue to flux over time, as experts consider

age-specific thresholds for symptom counts.

Further, there are differences between the DSM-5 criteria used to make the diagnosis in the United States and the ICD-10 criteria used to make the diagnosis in Europe and other parts of the world, although many investigators worldwide use the DSM system. Because of the difference in stringency of definition, DSM-5 ADHD is more prevalent than ICD HKD, a finding that could be easily misinterpreted to show that ADHD is more common in countries using DSM criteria than in countries using ICD-10 criteria (15). The reanalysis of the data of the National Institute of Mental Health (NIMH) Multimodal Treatment Study of children with ADHD (the MTA) found that only 145 of the 579 children who had DSM-IV combined type ADHD also met criteria for ICD-10 HKD (16). A further complication is whether all the inattentive presentation cases are detected in a given study.

Results of various prevalence studies in the United States and worldwide are similar: conservatively 5% in children and 2.5% in adults. The male:female ratio is about 2:1 in epidemiologically discerned samples, in contrast to 3 to 5:1 and even up to 9:1 in mental health clinic samples. Girls present more often with less disruptive symptoms, more attention problems and more internalizing problems such as depression and anxiety (17), while boys present with more disruptive behavior leading to clinical referral. Male sex, low socioeconomic status, and young age are associated with a higher prevalence of ADHD.

In preschoolers the hyperactive presentation is more common and the prevalence may vary from a low of 2% in the primary care setting to a high of 59% in a child psychiatry clinic (18). The symptoms of hyperactivity tend to decrease with age. In elementary school-age children, the combined type/presentation has been more frequently diagnosed, while the inattentive type was more common in middle and high school. As many as 60% of the childhood cases continue to have some symptoms as adults (19). Emotional symptoms are likely to persist and cause impairment in adults with ADHD (20–22).

Estimated ADHD Heritability Based on 6 Twin Studies

0.8 — Coolidge et al., 2000 (23)
0.7 — Hudziak et al., 2000 (24)
0.8 — Thapar et al., 2000 (25)
0.7 — Martin et al., 2002 (26)
0.7 — Rietveld et al., 2003 (27)
0.7 — Rietveld et al., 2004 (28)
FIGURE 5.1.1.2. Estimated ADHD heritability based on six studies.

ETIOLOGY

The etiology of ADHD is complex and most likely includes genetic and environmental factors.

Genetics

Studies have shown that ADHD is a phenotypically complex diagnosis that is strongly genetically influenced and is transmitted in families. In the past twin and adoption studies yielded an estimated heritability of about 75% (Figure 5.1.1.2) (23–28). A more recent analysis by Faraone et al (28a) found that genetic factors accounted for 60% of the heritability, with the rest being split between environmental influences and child specific environmental influences.

Recent genetic studies have been using endophenotypes as tools to detect the effects of individual genes. Endophenotypes are phenotypes that are assumed to be less complex in presentation and etiology than signs and symptoms of the clinical disorder but are still influenced by one or more of the same susceptibility genes as the disorder. Neuropsychological measures of inhibitory control and impairments in state regulation and delay aversion are considered potential candidates for ADHD endophenotypes (29–32). Other methods focus on distinct components or clusters of symptoms of the complex phenotypes that may be heritable and may characterize phenotypically homogenous groups of individuals.

There are several different chromosomal regions shared more often than expected by chance among ADHD family members. These regions have included 5p12, 10q26, 12q23, and 16p13 (33); 15q15, 7p13, and 9q33 (34); and 8q12, 11q23, 4q13, 17p11, 12q23, and 8p23 (35).

Association studies of candidate genes have looked for evidence that certain biologically relevant candidate genes may influence the susceptibility to ADHD (36).

Case control designs compare allele frequencies between patients with ADHD and non-ADHD control subjects, while family-based designs compare the alleles that parents transmit to ADHD children with those they do not transmit. If an allele increases the risk for ADHD, it should be more common among the transmitted alleles than the nontransmitted alleles. The data obtained in both study designs can be analyzed to derive odds ratio (OR) or relative risk (RR) statistics that assess the magnitude of the association between the risk alleles and the diagnosis of ADHD. An OR or RR of 1.0 indicates no association, greater than 1.0 indicates that the allele increases the risk for ADHD, and those less than 1.0 indicate that the allele decreases the risk for ADHD. The most studied candidate genes for ADHD are listed in Table 5.1.1.1 (37–123).

STRUCTURAL, FUNCTIONAL, AND ELECTROPHYSIOLOGIC

STRUCTURAL, FUNCTIONAL, AND ELECTROPHYSIOLOGIC FINDINGS IN THE BRAIN

Structural Findings in ADHD

Similarities between the symptoms of ADHD and symptoms observed in certain neurologic patients following damage to the prefrontal cortex (126) have prompted researchers to theorize that brain structural abnormalities may be at the root of ADHD symptomatology.

TABLE 5.1.1.1

CANDIDATE GENES FOR ADHD

Gene	Reference	Summary Findings
Dopamine Transporter Gene (DAT; SLC6A3)	Cook et al. (37); Waldman et al. (38); Dougherty et al. (39); Krause et al. (40); Todd et al. (41); Payton et al. (42); Muglia et al. (43); van Dyck et al. (44); Chen et al. (45); Smith et al. (46) Meta-analysis: Curran et al. (47); Gizer IR et al. (48); Azeredo LA et al. (49)	Pooled OR = 1.13
D2 Dopamine Receptor Gene (DRD2)	Case-control studies: Comings (50); Comings (51) Family-based studies: Rowe et al. (52); Kirley et al. (53); Huang et al. (54)	Pooled OR = 1.16 No conclusive results
D4 Dopamine Receptor Gene (DRD4–7)	Faraone et al. (55)—meta-analysis of case studies (CS) and family-based studies (FB)	Found a significant association between 7-repeat allele CR studies—pooled OR = 1.9 FB studies—pooled OR = 1.4
	Other positive case control studies: Payton et al. (42) Meta-analysis: Gizer et al. (48) Other positive family-based studies: Holmes et al. (56); Grady et al. (57); Arcos Burgos et al. (21) Negative case control studies: Qian et al. (58) Negative family-based studies: Mill et al. (59); Manor et al. (60); Kustanovich et al. (61); Smith et al. (46)	
Other DRD4 polymorphisms (120 bp repeat 1.2 kb; 240 allele FspI-521 C to T and Ava-II—616 C to G; 5'120-bp repeat)	McCracken et al. (62); Todd et al. (63); Barr et al. (64); Rowe et al. (65); Kustanovich et al. (61); Kustanovich et al. (66); Arcos Burgos et al. (21); Barkley et al. (18)	No conclusive results
D5 Dopamine Receptor Gene (DRD5)	Case control studies: Comings et al. (67) Family-based studies: Daly et al. (68); Barr et al. (69); Tahir et al. (70); Payton et al. (42); Kustanovich et al. (61); Kustanovich et al. (66); Mill et al. (71); Lasky-Su, Biederman et al. (72); Meta-analysis: Gizer et al. (48)	Probable association; results need independent replication

	Meta-analysis of family-based studies: Maher et al. (73); Lowe et al. (74); Manor et al. (75)	Significant association: pooled OR 1.2
D3 Dopamine Receptor gene (DRD3)	Barr et al. (76); Payton et al. (42); Muglia et al. (77); Coming et al. (67); Retz et al. (78)	Pooled OR = 1.2
Serotonin Transporter Gene (5-HTT; SLC6A4)	Case control studies: Retz et al. (79); Seeger et al. (80); Zoroglu et al. (81); Beitchman et al. (82) Family studies: Manor et al. (83); Kent et al. (84); Cadoret et al. (85) Meta-analysis: Gizer IR et al. (48)	Pooled OR = 1.31
Serotonin Receptor Genes (5HT2A)	Ribases M, Ramos-Quirgoa et al. (86)	Found evidence of association only with the combined ADHD subtype in adults (OR = 1.63) and children (OR = 1.49)
Aromatic L-amino acid decarboxylase (DDC)	Ribases M, Ramos-Quirgoa, et al. (86)	Strongly associated with adulthood (OR = 2.17) and childhood (OR = 1.90) ADHD
Norepinephrine Receptor Gene (SLC6A2, ADRA2A)	Case report studies: Comings et al. (67) Family-based studies: Barr et al. (87); McEvoy et al. (88); DeLuca et al. (89) Yang L, Qian Q, Li H, et al. (90)	No conclusive results
		One study suggests DNA variants of SLC6A2 and ADRA2A might alter the response to atomoxetine (results need further replication)
Dopamine Beta Hydroxylase Gene (DBH)	Case-control studies: Smith, 2003 (91) Family studies: Daly et al. (68); Payton et al. (42); Roman et al. (92); Wigg et al. (93); Hawi et al. (94); Barkley et al. (18)	Pooled OR = 1.33
Synaptosomal Associated Protein 25 Gene (SNAP 25)	Family-based studies: Hess et al. (95); Hess et al. (96); Barr et al. (97); Brophy et al. (98); Kustanovich et al. (61); Mill et al. (99); Kirley (100) Meta-analysis: Gizer et al. (48)	Pooled OR = 1.19
Tyrosine Hydroxylase Gene (TH)	Case control: Comings et al. (101) Family studies: Barr et al. (97); Payton et al. (42)	All studies negative
Catechol O COMT, Val108Met)	Family studies: Syvanen et al. (102); Barr et al. (103); Hawi et al. (104); Manor et al. (105); Tahir et al. (106); Payton et al. (42); Qian et al. (107); Beijsterveldt (108)	No significant association (pooled OR = 1.0)
Monoamine Oxidase A (MAO-A)	Case control: Manor et al. (109) Family studies: Payton et al. (42); Manor et al. (109); Lawson et al. (110)	All studies but one (Payton et al., 2001) found a significant association
Monoamine Oxidase B (MAO-B)	Ribases, Ramos-Quirgoa, et al. (86)	Specifically associated in the adult ADHD sample (OR = 1.90)
Noradrenergic	Comings et al. (111); Xu et al. (112); Comings et	No conclusive results

Receptors ADRA2A	al. (113); Barr, Wigg (114) Roman et al. (115)	
ADRA1C and ADRA2C	Comings et al. (111); Barr et al. (114); De Luca et al. (89)	No conclusive results
Serotonin Receptors HTR1B (G861C SNP)	Family studies: Hawi et al. (116); Quist et al. (117)	Pooled OR = 1.44
HTR2A (T102C; G1438A; His438Tyr)	Case control: Zoroglu et al. (81) Family studies: Quist et al. (117); Hawi et al. (116); Beijsterveldt et al. (108)	No significant association (pooled OR = 1.1)
Tryptophan Hydroxylase (TPH-SNP's A218C; 6526G)	Family studies: Tang et al. (124); Li et al. (125); Beijsterveldt et al. (108)	No conclusive results
Acetylcholine Receptors	Case control: Comings et al. (67)	No conclusive results
CHRNA4 and CHRNA7	Family studies: Kent et al. (120); Todd et al. (121)	
Glutamate Receptors GRIN2A	Family studies: Turic et al. (122); Adams et al. (123)	Contradicting results

TABLE 5.1.1.2

STRUCTURAL BRAIN ABNORMALITIES IN ADHD

Brain Region	Reference	Summary Findings
Prefrontal Cortex	Castellanos et al. (127); Filipek et al. (128); Overmeyer et al. (129); Castellanos et al. (123); Mostofsky et al. (130); Hill et al. (131); Durston et al. (132)	General findings in ADHD compared to healthy controls: smaller volumes in various areas, especially in the dorsolateral prefrontal and orbitofrontal regions and anterior cingulate
Caudate	Hynd et al. (133); Semrud-Clickeman et al. (134); Castellanos et al. (135); Castellanos et al. (127); Filipek et al. (128); Mataro et al. (136); Castellanos et al. (137); Castellanos et al. (123); Pineda et al. (138); Bussing et al. (139); Hill et al. (131); Castellanos et al. (140)	General findings in ADHD compared to healthy controls: smaller total caudate volume and/or smaller caudate head, but difference from normal lost with age
Pallidum	Aylward et al. (141); Castellanos et al. (127); Overmeyer et al. (142); Castellanos et al. (137)	General findings in ADHD compared to healthy controls: smaller pallidum volume
Corpus Callosum	Hynd et al. (143); Hynd et al. (144); Semrud-Clickeman et al. (145); Giedd et al. (146); Baumgardner et al. (147); Lyoo et al. (148); Castellanos et al. (149); Mostofsky et al. (150); Kates et al. (151); Hill et al. (152)	General findings in ADHD compared to healthy controls: smaller volumes especially in the posterior regions linked to temporal and parietal cortices
Cerebellum	Castellanos et al. (153); Filipek et al. (154); Berquin et al. (155); Mostofsky et al. (156); Castellanos et al. (149); Bussing et al. (157); Hill et al. (152)	General findings in ADHD compared to healthy controls: smaller volumes in various regions, including vermis

The most consistent structural brain imaging findings in children with ADHD have been significantly smaller volumes in the dorsolateral prefrontal cortex, caudate, pallidum, corpus callosum, and cerebellum (Table 5.1.1.2).

Neurocognitive studies of patients with ADHD also identified patterns of executive dysfunction in patients with ADHD (158,159) that are thought to reflect abnormalities in the functioning of the prefrontal cortex, therefore, supporting the hypothesis of an alteration of the prefrontal cortex neuroanatomy in ADHD. The robust symptom response to psychostimulant drugs that target the dopaminergic system, very well represented in the prefrontal cortex, further support this theory (160). With the introduction of totally automated imaging methods it has been possible to identify more widespread volumetric and cortical changes.

One of the most comprehensive longitudinal case control imaging studies was of 152 children and adolescents with ADHD (age range 5 to 18 years) and 139 age- and sex-matched controls (age range 4.5 to 19 years) completed at the National Institute of Mental Health (NIMH) from 1991 to 2001. The patients with ADHD had significantly smaller brain volumes on the initial scan in all regions (total cerebrum; cerebellum; gray and white matter for the four major lobes: frontal–temporal, parietal and occipital; unmedicated children with ADHD had significantly smaller total cerebral volumes and significantly smaller total white matter (161); the volumetric abnormalities persisted with age in total and regional cerebral measures and in the cerebellum except for the caudate nucleus volumes, which were initially abnormal in patients with ADHD but lost the diagnostic difference from controls during adolescence; developmental trajectories for all structures except the caudate remained roughly parallel for patients and controls during childhood and adolescence and are unrelated to stimulant treatment (162).

Prospective longitudinal case control brain MRI studies also identified abnormalities in the brain developmental trajectory in ADHD such as delayed prefrontal cortical development in children with ADHD compared to typical individuals (163–165). A prospective longitudinal study that followed ADHD patients into adulthood (166) found that fixed cortical thinning in the prefrontal cortex correlated with the persistence of the diagnosis in adulthood (167). Prefrontal cortical thinning and slowing of cortical development were also associated with inattention symptoms in healthy children in another study (168) and cortical thinning of the attention and executive function networks in adults was associated with ADHD in adults (169).

Twin studies using structural neuroimaging suggest that the volume of brain regions relevant to ADHD (subcortical and cortical volumes, left and right neocortex, variation of cerebellar volume) is under significant genetic control and might be used to define neuroimaging ADHD endophenotypes (170).

Brain Functional Abnormalities

New brain imaging techniques, including single-photon emission computed tomography (SPECT); positron emission tomography (PET); functional MRI (fMRI), and proton magnetic resonance spectroscopy (PMRS), have made it possible to obtain dynamic measures of brain metabolism at rest and during certain cognitive tasks. Most studies have found abnormalities in cerebral activation in ADHD, with a hypoperfusion of frontal and possibly striatal areas (Table 5.1.1.3). The studies looking at brain function during tasks that challenge the brain inhibitory control also show deficits in the activation of the brain inhibitory control area in the frontal and striatal regions. Because of the important role dopamine (DA) and the dopamine transporter (DAT) seem to have in the pathophysiology and response to treatment in ADHD, several imaging studies using ligands highly selective for the dopamine transporter sites have studied their density in ADHD subjects compared to controls. These studies consistently found an increase in the DAT binding in the striatum of ADHD subjects compared to controls. Several studies also showed a normalization of this brain function following treatment with methylphenidate.

Such functional investigative tools have opened a window on the dynamic nature of ADHD and started to elucidate the flexible and multidirectional causal relationship among brain structure, its neurochemistry, and brain function. Several recent studies found that stimulants prescribed for ADHD improved function and normalized neuroanatomy (215–217). Possible explanations for such findings are that either the stimulant itself directs the brain toward more typical development or the drug enhances function-driven normalization.

Multiple lines of evidence support the role of dopamine in the etiology and the response to treatment (Figure 5.1.1.3). The dopamine circuits are influenced by inputs from multiple areas of the brain involving other neurotransmitter systems, including norepinephrine and serotonin.

Table 5.1.1.4 presents one of the theories explaining the abnormal dopamine transporter density in ADHD subjects and the response to methylphenidate.

TABLE 5.1.1.3

FUNCTIONAL NEUROIMAGING STUDIES OF ADHD

Imaging Technique	Reference	Summary Findings
SPECT Studies	Lou et al. (171–174); Sieg et al. (175); Amen et al. (176); Gustaffson et al. (51); Langleben et al. (177,178); Spalletta et al. (179); Kim et al. (180,181)	General findings in ADHD compared to healthy controls: hypoperfusion in various cortical areas, especially in the frontal and prefrontal cortex, striatum and cerebellum
fMRI Studies	Sunshine et al. (182); Vaidya et al. (183); Bush et al. (184); Rubia et al. (185); Teicher et al. (186); Anderson et al. (187); Durston et al. (188); Schulz et al. (189); Tamm et al. (190)	General findings in ADHD compared to healthy controls: decreased cerebral blood flow to the frontal, prefrontal, and the basal ganglia; decreased activation of frontal/prefrontal regions

		and basal ganglia during certain cognitive tasks; atypical increase in activity in other brain areas possibly to compensate for hypoactivation; normalization of cerebral blood flow to frontal/prefrontal areas following administration of methylphenidate
PET Studies	Zametkin et al. (191,192); Matochik et al. (193,194); Ernst et al. (195–198); Schweitzer et al. (199–201)	General findings in ADHD compared to healthy controls: decreased glucose metabolism in prefrontal/frontal and other cortical areas and reduced metabolic rate in same areas during cognitive tasks
Positive DAT Binding SPECT Studies	Dougherty et al. (202); Dresel et al. (203); Cheon et al. (204)	Elevated DAT binding in ADHD compared to healthy controls compared to controls
Negative DAT Binding SPECT Studies	Van Dyke et al. (205)	No difference in striatum binding in ADHD compared to healthy controls compared with controls
Positive DAT Binding PET Studies	Spencer et al. (206,207)	Elevated binding in striatum in ADHD compared to healthy controls compared to controls
Negative DAT Binding PET Studies	Jucaite et al. (208)	No difference in DAT binding or D2 receptor binding in the striatum and decreased DAT binding in the midbrain between ADHD subjects and controls
		Significant correlation between DAT and D2 binding in the striatum and measures of hyperactivity
	Pedro Rosa-Neto et al. (209)	Estimated binding potential for D2/3 receptors in the striatum in ADHD within range of estimates obtained in healthy subjects; significant correlation between binding in the right striatum and severity of inattention and impulsivity; significant decrease in binding potential following administration of methylphenidate
PMRS Studies	Jin et al. (210)	Low *N*-acetyl aspartate/creatine ratio in globus pallidus in ADHD
	MacMaster et al. (211)	Elevated glutamate in the right prefrontal cortex and left striatum
	Yeo et al. (212)	Lower *N*-acetyl aspartate levels in girls with ADHD
	Courvoisie et al. (213)	Significantly higher ratios of *N*-acetyl aspartate; glutamate and choline/creatine in the frontal lobes of ADHD subjects
	Moore et al. (214)	Glutamatergic dysfunction in the anterior cingulated cortex in ADHD

	subjects compared to healthy controls and subjects with bipolar disorder

Electrophysiologic Studies

Electroencephalograms (EEGs) provide information about the background electrical activity of the brain with good temporal resolution but poor spatial resolution. EEG studies of patients with ADHD were first done as early as 1938 (218) when they included mostly qualitative EEG studies that used visual evaluation of paper recordings of the EEG. Most studies consistently found elevated levels of slow-wave activity in comparison to normal children, with the most reliable measure being the relative theta power and reduced amounts of relative alpha and beta waves.

Several studies have looked at EEG as a diagnostic tool and reported that the theta/beta ratio could discriminate ADHD subjects from control subjects with sensitivity and specificity (219–222). However, more recent studies have noted attenuation of the difference in theta/beta ratio over time due to the theta/beta ratio of normal controls approaching that of individuals with ADHD, possibly as a result of sleep deprivation (223). Several models of ADHD and ADHD presentations have been proposed based on EEG studies: the Maturational Lag Model; the Developmental Deviation Model; and the Hypoarousal Model (Table 5.1.1.5). All models fail to account for the complex clinical presentation in ADHD.

Event-Related Potentials

Event-related potentials (ERPs) provide information about the brain electrical activity underlying sensory and cognitive brain processes in response to stimuli. The small subject numbers, the use of different types of task performance indicators and reward systems, and other methodologic flows have made the results of most of the studies to date difficult to interpret (241).
FIGURE 5.1.1.3. Dopamine synapse. Genetic studies indicate that patients with ADHD have a higher rate of certain polymorphisms for the dopamine and other receptors and for the dopamine transporter, resulting in either lower sensitivity of the receptor or faster reuptake of dopamine molecules. Stimulant drugs inhibit reuptake, keeping each dopamine molecule longer in the synaptic cleft so that it is available to stimulate the receptors longer. Similar considerations apply also to norepinephrine, another neurotransmitter believed to be involved in ADHD.

TABLE 5.1.1.4

THE DOPAMINE TRANSPORTER AND ADHD

Theory	Rationale
Abnormal DAT binding as a "trait"	"Hypertrophy" of the dopaminergic neurons as a result of inadequate pruning during neurodevelopment genetic abnormalities
Abnormal DAT binding as a "state"	Result of processes compensating for abnormal (increased or decreased)

	dopamine transmission an attempt to increase efficiency of dopamine clearing resulting from abnormalities at the dopamine synapse level (excess dopamine production and/or release; decreased vesicular storage; increased activity of D1–D5 receptors; abnormal receptor–effector coupling)

With the development of molecular genetics, attempts have been made to identify electrophysiologic endophenotypes of ADHD. A meta-analytic review of twin studies of electrophysiologic measures indicates that genetic factors contribute significantly to both EEG and ERP measures, with significant heritability scores for the EEG alpha power and alpha peak frequency and ERP P3 amplitude (242). More studies are needed to refine such endophenotypes (243).

Special Etiologic Subgroups

Because ADHD is a phenomenologic diagnosis rather than etiologic, there can be various causes manifested through the same symptom constellations. Genetic predisposition, of course, is a major cause, but genes can exert their influence only through interaction with the environment and other genes. The pathogenetic mechanisms for expression of various genes in interaction with various environments—physical, chemical, nutritional, familial, social—can vary widely from one individual to another. The multiple-allele polymorphisms described above allow for multiple environmental sensitivities or special environmental needs, and there are probably further polymorphisms not yet discovered. For example, there appears to be a subgroup of children with ADHD who have some kind of food or food additive sensitivity demonstrated in placebo-controlled studies (124,125,244,245). Another very small subgroup has thyroid abnormality intimately linked to ADHD symptoms (246,247). Heavy metal poisoning can cause ADHD symptoms, and at least one study suggested that in cases of lead toxicity, ADHD symptoms improve as much (or more) with deleading as with a stimulant drug (248). It is possible that because of genetic differences in enzymes and other metabolic features, some individuals may be more sensitive to heavy metal poisoning than others. Some anticonvulsants can make ADHD symptoms worse.

Recent studies have found some evidence that tryptophan depletion and vitamin D deficiency may be linked to ADHD (249–251). Many authors believe that thresholds of vitamin and mineral requirements vary from person to person, so that some may be more susceptible to borderline deficiency symptoms.

TABLE 5.1.1.5

EEG-BASED MODELS OF ATTENTION-DEFICIT HYPERACTIVITY DISORDER

Model	Rationale	EEG Characteristics	Reference
Maturational Lag	1. ADHD results from a developmental lag in central nervous system functioning. 2. EEG measures in the ADHD subject would be considered normal in a younger child and EEG findings mature in a normal fashion.	Increased centroposterior relative delta; increased relative theta across the scalp; decreased frontocentral relative beta; decreased relative alpha across the scalp; greater levels of theta and deficiencies of alpha and beta in comparison to the control group	Kinsbourne et al. (224); Satterfield et al. (225); Matsuura et al. (226); John et al. (227); Clarke et al. (228); Lazzaro et al. (229)
Developmental Deviation	1. ADHD results from an abnormality in central nervous system functioning. 2. Beta levels in the ADHD combined group were greater than mean values for control group; the theta levels were greater than control groups; less relative alpha compared to control group		Klinkerfuss et al. (230); Wikler et al. (231); John et al. (232); Clarke et al. (233,234)
Hypoarousal	1. ADHD results from cortical hypoarousal. 2. EEG measures in the ADHD subject indicate lower levels of beta activity during cognitive tasks. 3. EEG findings of hypoarousal in the ADHD subject should correlate with other functional measures of the brain activity showing decreased cortical activation.	Reduced suppression of alpha waves; increased frontal relative theta; decreased relative beta suppression across the scalp;	Satterfield and Cantwell (235); Satterfield et al. (236,237); Grunewald-Zuberbier et al. (238); Ackerman et al. (239); Lubar et al. (240)
Overaroused		Excess beta activity	

DIAGNOSIS AND CLINICAL FEATURES

Importance of History

ADHD is a diagnosis primarily made by history: by caregiver report (or in the case of some adolescents and adults, by self-report) of a chronic pattern of inattentiveness, overactivity, and/or impulsiveness. Rarely is a short sampling of behavior in an office visit adequate to detect the symptoms, and even then the diagnostician needs caregiver confirmation of their chronicity and pervasiveness. Often a child with ADHD can appear calm and attentive in a novel setting with an adult one-on-one,

especially a strange adult. Therefore, careful collection of the observations of parents, teachers, and other caregivers (bus drivers, coaches, sitters) is the most essential diagnostic strategy.

Parent and Teacher Rating Scales

An excellent way to collect caregiver observations is by using one of the many standardized rating scales. Probably the best ones are those that use the actual DSM-IV symptoms rated on a standard metric, usually 0 to 3, from no symptom to severe. Examples include the ADHD Rating Scale (252) and the SNAP (Swanson, Nolan, & Pelham, adhd.net), which have only DSM symptoms, and the Conners 3 long forms (253) which have the DSM symptoms embedded in a longer scale. When counting symptoms, a rating of 2 or 3 on the 0 to 3 scales is usually considered as the presence of the symptom. Numerous other scales are also useful and have been used in research and clinical practice.

Family History

Additional diagnostic information can come from family history, both positive and negative. For example, relatives with ADHD help to confirm the diagnosis. On the other hand, the absence of relatives with ADHD, coupled with either history of traumatic stress or family history of bipolar disorder, thyroid disorder, or severe anxiety may alert the diagnostician to the possibility that the patient's symptoms may be another disorder mimicking ADHD and point the direction for further investigation.

Mental Status Examination

The main value of mental status examination is to rule out other mental disorders that might better explain the symptoms (Criterion E of DSM-5). These include psychosis, bipolar disorder, depression, autism, and severe anxiety—especially posttraumatic stress disorder—as well as intellectual disability. A reasonable mental status examination for this purpose would include appearance/demeanor, orientation, alertness, speech clarity and content, affect, ability to develop rapport, relevance and logic of thought processes, some estimate of cognitive ability, queries about depressive or other mood symptoms, worries, fears, obsessions, compulsions, hallucinations, and traumatic events, and some projective elicitation such as drawing, three wishes, or fable completion.

Physical Examination and Medical History

Although there are no diagnostic physical signs in ADHD (when abnormalities occur, they usually reflect a comorbid disorder such as intellectual disability, cerebral palsy, or genetic syndromes), a physical examination and medical history can be useful in ruling out other mimicking disorders and in discovering or confirming the common comorbidity of developmental coordination disorder. Also, the presence of soft neurologic signs and/or minor physical anomalies may somewhat increase confidence in the ADHD diagnosis, even though there is no 1:1 link. Soft neurologic signs are nonfocal motor deficits that include deficits in balance, motor planning and control, and sensory integration (254,255) (Table 5.1.1.6). Gustaffson et al. also found a significant correlation between the soft neurologic signs and decreased cerebral blood flow measures in the frontal lobes bilaterally in children with ADHD. At this time, functional imaging is not a part of the routine workup of ADHD. Physical examination would note hyperdynamics or hypodynamics, abnormal deep tendon reflexes, fine or coarse skin or hair, and any other signs of endocrine disorder, as well as allergic stigmata (swollen eyes, darkened lids, nasal congestion, and allergic salute) and pallor of nail beds or conjunctivae. Positive findings should, of course, prompt appropriate laboratory tests. The diagnostician should inquire about things like food sensitivities (especially in younger children), dietary imbalance, cardiac problems, and heat or cold intolerance. Prominent allergic signs suggest a possible etiologic or exacerbating condition (e.g., food intolerance, atopy).

TABLE 5.1.1.6

SOFT NEUROLOGIC SIGNS IN ADHD

Clinical Finding	Putative Explanation
Difficulties performing repetitive motor tasks (such as hand flipping; foot rocking; serial thumb to finger opposition)	Impaired ability to use cognitive control to alternately inhibit and excite motor activity to maintain a regular cadence
Difficulties performing sequential timed tasks (such as foot rocking; hand flipping; serial finger)	Impaired ability to use cognitive control to adjust motor performance) flexibly in a multistep task
Difficulties maintaining gait and balance (sustained motor stance; tandem balance)	Difficulties maintaining balance; integrating proprioceptor input/body position sense; abnormal vestibular function; etc.

Presentations

The distinction among presentations (types) is more dimensional than categorical. For example, a child with six inattentive symptoms and five hyperactive-impulsive symptoms would have predominantly inattentive presentation, while someone with six symptoms of each kind would have combined presentation ADHD. Further, the presentation/type does not even firmly predict the ratio of the two kinds of symptoms. For example, six inattentive and five hyperactive-impulsive would make inattentive presentation, but nine inattentive and six hyperactive-impulsive symptoms would

make combined presentation despite having a greater excess of inattentive symptoms than the first symptom profile. Despite this threshold-definition problem, some experts believe that a substantial proportion of inattentive presentation, those who are sluggishly hypoactive, may actually constitute a distinct disorder with different etiology. In any event, the inattentive presentation tends to be referred less often for treatment and tends to be missed diagnostically more often, especially if of high enough intelligence to get by in school without using full potential.

Comorbidity

ADHD has a high rate of comorbid psychiatric disorders. Half of clinical samples have oppositional defiant disorder (ODD) or conduct disorder (CD), 25% to 30% have anxiety disorder, and 20% to 25% have a learning disorder (256,257). There is increased risk for mood disorders (which may develop later). Although the rate of comorbid Tourette's is low (about 2%), it is much higher than in the random population or in other psychiatric disorders. Comorbidity can introduce some diagnostic challenges because the comorbid disorders can mimic ADHD, with overlapping symptoms, so the diagnostician must differentiate between comorbidity and primary diagnosis. Table 5.1.1.7 presents some comparisons and differences.

TABLE 5.1.1.7

SOME MENTAL DISORDERS THAT CAN MIMIC ADHD: THEIR OVERLAPPING OR SIMILAR SIGNS/SYMPTOMS

ADHD Symptoms	Depression	Bipolar (Manic)	Anxiety, Including PTSD	Psychosis	Au
Inattentiveness, distractibility, forgetfulness, losing things, careless mistakes	Impairment of concentration and memory; preoccupation with mood	Flight of ideas, thought racing, distraction by delusions or grandiosity	Preoccupation with worry; intrusive memories; flashbacks, psychic numbing, hypervigilance	Withdrawal from reality, preoccupation, loose association, "distraction" by	Dis
Failure to finish tasks or activities; reluctance to start if needs sustained mental effort	Fatigue, anergia, loss of interest	Flight of ideas/activities; grandiosely above common tasks	Fear-induced paralysis of function; afraid to try, expecting failure; avoiding of reminders	hallucinations As above; abrupt change of activity	Ab
Difficulty organizing	Anergia, cognitive impairment	Flightiness		Psychotic fragmentation	
Hyperactivity, fidgeting/squirming	Agitation	Hyperactivity, driven quality	Panic, agitation, anxiety-driven	Psychotic agitation,	Hy

restlessness, always on the go			restlessness, “nervousness”	response to hallucinations	f
Excessive talking	Agitated complaining	Pressured speech	Anxious verbosity, obsessions, verbal	Talking to hallucinations	Co s r
Impulsive blurting of answers, interrupting, intruding	Preoccupied complaining (pain, worry)	Pressured speech, flight of ideas, impulsive poor judgment	rituals Anxious eagerness; reenactments	Responding to hallucinations	Ob p (
Impatience, easy frustration, difficulty waiting	Easy frustration	Pressured hyperactivity and impulsiveness	Intolerance of delay that builds suspense or reminds of trauma	Lack of social orientation	Ea
Irritability	Irritability	Irritability	Anger when rituals frustrated	Paranoid irritability	Irri v r i
Restless sleep, lability, instability (emotional and physiologic)	Insomnia	Insomnia Labile affect	Insomnia or nightmares Physiologic instability, nervousness	Nocturnal agitation Psychotic unpredictability	Ins u
Distinguishing from ADHD	Depressed mood, anorexia, weight loss, suicidal ideation, guilt feelings, psychomotor slowing, mutism, fatigue	F.H. of mood disorder; extreme driven quality; sometimes episodic; prominent mood: irritable, grandiose; possible appetite change, weight change	Phobias, worries, stress-induced onset, obsessions, compulsions, perfectionism, tremor, physiologic symptoms (palpitations, SOB, sweating), posttraumatic play	Delusions, poverty of thought, disorientation, command hallucinations, inappropriate affect	Im r (I r f s i

NEUROPSYCHOLOGICAL TEST RESULTS

A great deal of research done within the past 30 years supports the view that ADHD is a heterogeneous disorder related to multiple neuropsychological deficits (31). Executive functions are neurocognitive processes that maintain an appropriate problem solving set to attain a future goal (258). Executive function tasks include response inhibition and execution; working memory and updating; set shifting and task switching; interference control; planning and organization; vigilance; visuospatial orienting; and verbal and spatial working memory. Children with ADHD, for example, exhibit significant working memory deficits compared to typically developing children (259). Executive functions employ multiple neural networks that involve the thalamus, basal ganglia, and prefrontal cortex. The most common neuropsychological test results measuring different aspects of executive functioning in ADHD are listed in Table 5.1.1.8.

Several theories have been developed based on the neuropsychological profile of children with ADHD.

1. The deficit in inhibitory control theory suggests that the general pattern of executive impairment is caused by developmental abnormalities in inhibitory control processes (260). A meta-analysis of neuropsychological studies in adults found a somewhat different profile of neurocognitive deficits compared to children and adolescents, with deficits related mostly to impairment in measures of verbal memory, focused attention, sustained attention, and abstract verbal problem solving with working memory. Simple alertness tasks were less impaired than more complex attention tasks (261).
2. The delay aversion theory posits a biologically based impairment in the ability to tolerate delay and its consequences on behavior and cognitive style. A test used to measure ability to tolerate delay is the Choice Delay Task (262,263).
3. In the cognitive energetic model (264), neurocognitive performance deficits in ADHD are determined by information processing abnormalities at the computational (encoding, search, decision, and motor organization) and state levels (effort, arousal, and activation). The model proposes the existence of three energetic pools: effort (necessary energy to meet the demands of the task); arousal (time locked to stimulus processing) and activation (tonic changes in physiologic activity in significant brain areas, including the basal ganglia and

corpus striatum), and the existence of a management or evaluation mechanism associated with planning, monitoring, detection, and correction of errors that overlaps with the concept of executive functions in other theories.

4. The sluggish cognitive tempo theory proposes that inattention presents differently in ADHD without hyperactivity compared with combined presentation (265), the main features including slow retrieval and information processing; low levels of alertness; and mild problems with memory and orientation. Further studies are needed to answer the question of whether the group of sluggish cognitive tempo children may represent a distinct category of ADHD with a different pathophysiology or may even represent a different disorder altogether.
5. The multiple pathway model emphasizes the parallels between the core deficits in ADHD as defined by major theories of ADHD and relevant temperament and personality domains, in particular effortful control and regulation (266,267).

COURSE AND PROGNOSIS

Up to 60% of childhood cases continue symptomatic into adulthood (268,269). The ratio of males to females in adult samples approximates 2:1 or even close to 1:1, much more equal than in childhood, where it is more likely 4 or 5 to 1 in clinical samples. The change in sex ratio of clinical cases in adulthood may partly reflect a sex difference in willingness to seek help, or possibly girls who had not shown enough problems in school to be identified, finally realizing deficits as grown women. ADHD can seriously impair the quality of life of children with ADHD (270,271) and have co-occurring aggressive and depressive symptoms.

The manifestations of ADHD change over the course of life (Figure 5.1.1.4). Just as normal children develop better impulse control, attentional focus, other executive function, and ability to remain calm as they mature, so do those with ADHD, just at a slower pace, lagging behind their age mates. Childhood ADHD severity and childhood treatment significantly predicted the persistence of ADHD in adulthood in the National Comorbidity Survey Replication Study (272). ADHD symptoms in adults are more heterogeneous and subtle, leading some researchers to suggest the need for different diagnostic criteria in adults.
FIGURE 5.1.1.4. Course of different ADHD symptoms over the life span. Hyperactivity tends to wane with maturity, being replaced by a feeling of restlessness. Impulsivity also tends to wane except for a possible blip in adolescence under the influence of “raging hormones.” The most persistent cluster of symptoms is inattentiveness, with the main adult manifestations being disorganization, difficulty managing money, keeping schedules, and sticking with a relationship or job. (Reproduced with permission from Arnold LE: *Contemporary Diagnosis and Management of ADHD.* Newtown, PA: Handbooks in Health Care, 2004.)

Hyperactivity is the most likely symptom to be outgrown. Adolescents and adults with ADHD, even those who started with combined presentation, may have only an inner feeling of restlessness. The most persistent symptom cluster involves inattention, distractibility, disorganization, and failure to finish things. Males with a childhood history of significant hyperactivity, impulsivity, and disruptive behavior disorder comorbidity are more likely to develop polysubstance abuse and adult antisocial behavior. Adults with ADHD may struggle with frequent job changes, frequent partner changes, divorce, difficulty with schedules and money management, and driving accidents. Girls and women with ADHD have a higher rate of unwed pregnancy than those who do not have ADHD. Adults with ADHD may present with significant self-esteem issues and feelings of hopelessness and helplessness related to ongoing difficulties in managing everyday life. Several follow-up studies have

found a high rate of major depression in adult patients with ADHD. Effective treatment significantly improves quality of life. Ambivalence about the existence of an adult ADHD diagnosis and concerns over prescribing psychostimulants with a high potential for abuse have made it difficult for adults with ADHD to receive treatment. Minority status, female sex, and low income were found in several studies to predict failure to be diagnosed and treated (153,273).

TREATMENT

Because ADHD is a chronic and pervasive disorder, affecting all areas of function, the treatment plan must be farsighted, comprehensive, and flexibly adapted over time to changing needs. The commitment of patient and family to the plan must be cultivated. This implies that treatment must be not only effective, but also feasible, palatable, and affordable for the particular patient. Therefore, treatment planning has to be individualized, with consideration for family preferences. From the beginning, the child, as star of the therapeutic team, should be involved in planning, with an eye toward the day when he or she has to assume responsibility for his or her own treatment as an adult. Other members of the team—physician, teacher, psychologist, and other professional—can come and go; even parents are eventually outgrown; but the patient is permanently involved.

The necessary gradual assumption of personal responsibility for managing the disorder should be discussed periodically with the child and adolescent. For the younger child, this can involve parents. For example, for a 10-year old, lay out the fact that in 8 years, the child will have to assume responsibility for self and discuss how parents can coach and support in gradual assumption of responsibility. A 14-year old can be seen alone briefly and reminded that he or she has only 4 years to prepare for personal responsibility; it may be useful to inquire if the idea scares them before asking how they plan gradually to take more responsibility. Attention to such psychosocial and psychodynamic aspects of management is important especially for patients who are treated mainly with medication. See also Psychoeducation below.

Established Treatments

Two treatment modalities have been endorsed by both the American Academy of Child and Adolescent Psychiatry (154) and American Academy of Pediatrics (150,152,274). They are behavioral treatment and the FDA-approved agents (amphetamine, methylphenidate, atomoxetine, guanfacine, and clonidine). Additional drugs are expected to be added to the list of agents with an approved indication for ADHD. The flow chart of evaluation and treatment recommendations published by the American Academy of Pediatrics is reproduced in Figure 5.1.1.5. In acute and medium-length studies (up to 2 years) medication generally outperforms behavioral

treatment for symptom suppression, but three-fourth of children with ADHD can be managed with intensive behavioral treatment alone, and the combination offers several advantages, including equal or better results with a lower medication dose, saving side effects (245,275,276).

For some comorbid subgroups, such as ADHD combined with both anxiety and ODD/CD, the combination is impressively more effective (145,277). Behavioral treatment appears especially effective in the presence of comorbid anxiety.

Behavioral Treatment

Behavioral treatments are based on social learning theory. Behaviors that are reinforced increase in frequency and those that are not reinforced in some way (or are punished) tend to extinguish. A number of practical behavioral treatments can be implemented from the first contact. These include star charts for target behaviors, clear house rules, written or pictorial instructions making use of the visual channels if auditory instructions seem unattended to, and contingencies for doing various things. With more time and effort, more refined interventions can be set up, such as a home token economy or a daily report card to tie school behavior to home reinforcement. There are several programs for providing parent training in behavioral management, now called parent management training (PMT). For younger children and milder cases, these may provide sufficient intervention, but once diagnosed, a case should be monitored over time. Sometimes additional need for treatment emerges as the child progresses to more challenging academic stresses.

Pharmacologic Treatment

Most psychiatric drugs have some evidence of benefit in ADHD (notable exceptions being the selective serotonin reuptake inhibitors), but only a few have a Food and Drug Administration (FDA)-approved indication (Table 5.1.1.9A). The evidence for many of the others, such as tricyclic antidepressants, bupropion, monoamine oxidase inhibitors, and modafinil, is nevertheless rather good, with multiple placebo-controlled trials (Table 5.1.1.9B). However, some have only open trials or a single-controlled trial. Tables 5.1.1–5.1.9 show approximate relative effect sizes (the number of standard deviations by which active drug differs from placebo).

With any of the drugs, it is important to start low and titrate, preferably weekly, to individual optimal effect. Generally for school-age children, the smallest size stimulant dosage marketed is a good place to start. Because of wide individual variability in sensitivity, the size of the patient is only a rough guide to dose: One 30-kg child may require and tolerate 30 mg/day of amphetamine while another 30-kg child has an optimal response to 5 mg/day, with severe side effects above 10 mg. Clinical art is required to optimize the benefit and minimize side effects by size of

dose, timing, and management of time–action effects such as "evening rebound" with stimulants. Generally, the new extended-release preparations yield a smoother effect with fewer ups and downs. They also avoid the necessity of taking pills at school, which some children find stigmatizing. For such reasons, extended-release formulations of stimulants are preferred, and titration can be initiated directly with one of them without any need to first establish dose with immediate-release tablets.

1 Child presents with diagnosis of ADHD.

2 Clinician, parents, child, and teacher should:
(1) Identify target outcomes.
(2) Develop a comprehensive treatment plan.
(3) Assess response to the treatment plan.
• Primary care clinicians should establish a treatment program that recognizes ADHD as a chronic condition.
• The physician recommends stimulant medications* and/or behavior therapy to improve target outcomes.

3 Is response to treatment plan adequate? — No → 8; Yes → 4

8 Is the child on stimulant medication? — No → 9; → 11

9 1. Consider adding stimulant medication.* 2. Reinforce behavior therapy. → 10

10 Go to Box 2, Step 3.

4 Clinician monitors routinely.
• Clinician should periodically provide systematic follow-up to monitor target outcomes and adverse effects.
Yes → 5

11 Have all stimulant medications* been tried? — No → 12; → 14

12 1. Consider adding stimulant medication.* 2. Reinforce behavior therapy. → 13

13 Go to Box 2, Step 3.

5 Is response to treatment plan adequate? — No → 6; → 7

6 Go to Box 2.

7 Go to Box 4.

14 Is adherence to stimulant medication* or behavior therapy poor? — No → 16; Yes → 15

16 Go to Box 17.

15 Go to Box 2. Steps 2 and 3.

17 Continued from Box 16.

18 Is the diagnosis correct? — No → 19; Yes → 20

19 Exit guideline and seek appropriate treatment.

20 Were coexisting conditions missed? — No → 21; Yes → 23

21 Are target symptoms appropriate? — No → 22; Yes → 24

22 Clinician should consider second-line medications after all stimulants* have been tried.

23 Clinician should evaluate and treat coexisting conditions.

24 Go to Box 2.

* Excluding pemoline. Another FDA-approved option is atomoxetine (Strattera©), approved since the guideline was published.
Used with the permission of the Academy of Pediatrics. From Clinical practice guideline: treatment of the school-aged child with attention deficit/hyperactivity disorder. *Pediatrics* 108:1033–1044, 2001.

FIGURE 5.1.1.5. Clinical guidelines by American Academy of

Pediatrics, which were written before availability of atomoxetine, which, as an FDA-approved treatment for ADHD, should be considered after a stimulant before resorting to off-label drugs. (From American Academy of Pediatrics: Clinical practice guideline for the school-age child with ADHD. *Pediatrics* 108:1033–1048, 2001.)

TABLE 5.1.1.9A

DRUGS WITH FDA APPROVAL FOR ADHD

Generic Name	Brand Name	Usual Daily Dose[c] mg (mg/kg)
Stimulants (ES 0.7–1.8)		
Amphetamine, racemic (dextro–levo)[a] dextroamphetamine[a,b]	Evekeo®	10–40 (0.3–1)
	Dexedrine® DextroStat®	5–30 (0.2–0.7)
mixture 3/4 d-, 1/4 L-amphetamine[a,b] mixed amphetamine salts (MAS)	Adderall®	5–40 (0.2–1)
	Adderall® XR	5–40 (0.2–1)
methamphetamine[b,d]	Desoxyn®	5–25 (0.2–0.7)
	Adzenys XR	6.3–12.5 (0.2–0.5)
	Dyanavel XR	2.5–20 (0.1–0.8)
lisdexamfetamine dimesylate	Vyvanse	20–70
Methylphenidate, racemic threo[a,b]	Ritalin®,	10–60 (0.3–1.5)
	Methylin®	10–60 (0.3–1.5)
	Ritalin® LA	20–60 (0.6–1.5)
	Metadate®	10–60 (0.3–1.5)
	Metadate® CD	20–60 (0.6–1.5)
	Aptensio XR	10–60 (0.3–1.5)
	Metadate ER	20–60 (0.6–1.5)
	Quillivant XR	20–60 (0.6–1.5)
	QuilliChew ER	20–60 (0.6–1.5)
osmotic release[a,b]	Concerta®	18–72 (0.4–1.8)
Transdermal release	Daytrana patch	10–30 (0.3–0.7)
dextro-threomethylphenidate[a,b]	Focalin™	5–30 (0.2–0.7)
	Focalin XR™	5–30 (0.2–0.7)
Nonstimulants with FDA-Approved Indication (ES 0.5–1.4)		
Atomoxetine[a,b]	Strattera®	18–100 (0.7–1.4)
Guanfacine XR[a,b]	Intuniv	1–4 (0.05–0.12 mg/kg/day)
Clonidine XR[a,b]	Kapvay	0.1–0.4 mg

[a]Supported by controlled studies.
[b]FDA-approved indication for ADHD.

[c]Usual daily dose should not be interpreted as either a cap or a minimal effective dose if a higher or lower dose is clinically indicated in individual cases. Actual patient doses must be individually titrated using direct teacher and parent information.
[d]Although it carries an FDA-approved indication for ADHD, methamphetamine, in contrast to other forms of amphetamine, is not favored by many experts because of suspected neurotoxicity in animal data.
∆Because only 5/6 of the MPH in the osmotic-release form is released, 72 mg = 60 mg of other MPH preparations.
ES, effect size, the number of standard deviations different from placebo or from pre-drug measure. It is a measure of clinical significance. An ES of 1 is considered large, 0.5 medium.
Reproduced with permission from Arnold LE, *Contemporary Diagnosis and Management of ADHD.* Newtown, PA: Handbooks in Health Care, 2004.

Labeled and Off-Label Drugs

The drugs with currently approved FDA indications for ADHD are the stimulants, atomoxetine, guanfacine, and clonidine, with others being developed for that indication. Some antipsychotics also have an indication for "childhood hyperactivity" grandfathered from previous use in the 1970s, and there is no doubt that antipsychotics have a moderate benefit for hyperactive symptoms. However, because of their greater risk and less impressive benefit, they would usually be a last resort, logically used mainly when a stimulant worsens the symptoms. Some off-label drugs with good evidence would be preferred to antipsychotics early in the search for an effective medication. Antidepressants other than selective serotonin reuptake inhibitors (SSRIs) have many placebo-controlled studies supporting their use. These include tricyclics, monoamine oxidase inhibitors (MAOIs), and bupropion. For children the effect is not on average as good as for stimulants, but some individuals may respond better, and comorbid depression or anxiety might point toward considering one of them. The danger of interaction with food amines would limit the feasibility of MAOIs for children. Another class with reasonable evidence is the alpha-agonists; of these, guanfacine has the advantages over clonidine of longer half-life and less sedation. They may be good for severely overaroused agitation and comorbid aggression. Clonidine is often used at bedtime alone to promote sleep, although the practice has been questioned on safety grounds if used in conjunction with daytime stimulants. Diphenhydramine, an antihistamine with some dopamine effect, was an arcane treatment before more modern drug development; for a few patients, especially those whose behavior fluctuates with allergy, it may have considerable benefits. Table 5.1.1.10 lists some of the advantages and disadvantages of the main drugs.

Educational Plan and Psychoeducation about Disorder

Education is important in two ways in ADHD: as a problem area that needs to be addressed and as a treatment modality. Most children with diagnosed ADHD have

some problem with academic performance; in fact, that is often what brings them to clinical attention. Although most are able to function in a regular classroom with appropriate treatment and support, some will need an individual educational plan (IEP) or even a special class or resource room. This is particularly so for the 20% to 25% with comorbid learning disorders. Parents may need some coaching in obtaining appropriate educational services for the child, such as is required by PL 94–142 (Education for All Handicapped Act), IDEA (Individuals with Disabilities Education Act), or section 504 of the Civil Rights Act. Children with learning disorders are likely to be covered by the first two mandates, and those without a specific learning disorder are usually covered by section 504, which provides for "other health impaired."

TABLE 5.1.1.9B

OTHER DRUGS USED FOR ADHD

Generic Name	Brand Name	Usual Daily Dose[b] mg (mg/kg)
Not all of the following drugs have been documented as effective by well-controlled studies, let alone approved by the FDA for ADHD.		
Antidepressants (ES 0.5–1.5)[c]		
Imipramine (TCA)[a]	Tofranil®	20–100 (0.7–3)
Desipramine (TCA)[a]	Norpramin®, Pertofrane®	20–100 (0.7–3)
Amitriptyline (TCA)[a]	Elavil®, Endep®	20–100 (0.7–3)
Nortriptyline (TCA)	Pamelor®	10–50 (0.4–2)
Bupropion[a]	Wellbutrin®	75–300 (3–6)
Clomipramine (TCA)[a]	Anafranil®	25–100
Tranylcypromine (MAOI A + B)[c]	Parnate®	5–15
Clorgyline (MAOI A)[a]		5–20
Pargyline (MAOI)		Eutonyl®
Venlafaxine[d]	Effexor®	25–100 (1.4)
SSRIs (e.g., fluoxetine[d])	Prozac®	5–40
Miscellaneous (ES variable)		
Buspirone (ES < 1)	BuSpar®	5–30 (0.2–0.6)
Diphenhydramine	Benadryl®	75–150
Nicotine (adults only, ES > 1)[a]	(lower dose for nonsmokers)	7–21 mg patch
Modafinil (ES ~ 1)[a]	Provigil®	50–400
Anticonvulsants (ES up to 1.0)		
Carbamazepine[a]	Tegretol®	50–800, serum level
Valproate	Depakote®, Depakene®	serum level
Phenytoin	Dilantin®	50–300
Antipsychotics (ES usually about half of stimulants)[f]		

Thioridazine[a]	Mellaril®	25–150 (1–6)
Haloperidol[a,e]	Haldol®	0.5–5.0 (0.03–0.075)
Chlorpromazine[a,c]	Thorazine®	25–150 (1–6)
Risperidone	Risperdal®	0.25–2.0 (0.01–0.1)
Precursors (ES < 0.6, short term)[g]		
Deanol (possible precursor of acetylcholine)	Deaner®	>500
Tryptophan (precursor of serotonin)		(70–100)
Tyrosine (precursor of dopamine and norepinephrine)		(100–140)
Phenylalanine (precursor of dopamine and norepinephrine)		(100–140)
Levo–DOPA (precursor of dopamine and norepinephrine)		Carbidopa
Others		
β-blockers (e.g., propranolol)	Inderal®	10–300
Caffeine		100–450

[a]Supported by controlled studies.

[b]Usual daily dose should not be interpreted as either a cap or a minimal effective dose if a higher or lower dose is clinically indicated in individual cases. Actual patient doses must be individually titrated, using direct teacher and parent information.

[c]No antidepressants are FDA approved for ADHD, despite well-controlled studies demonstrating efficacy for many of them. In fact, some (but not all) studies show imipramine, desipramine, amitriptyline, and tranylcypromine equal to stimulants, although with worse side effects. For adults, they may equal stimulants despite not seeming to benefit attention as much as behavior.

[d]Despite a report of a positive open trial of fluoxetine, most experts do not consider selective serotonin reuptake inhibitors (SSRIs) generally effective for ADHD core symptoms, in contrast with the documented effectiveness of other antidepressant classes. The newer antidepressants, with both serotonin and catecholamine action (such as venlafaxine, mirtazapine, and nefazodone) are expected to be effective. The number of standard deviations different from placebo or from pre-drug measure. It is a measure of clinical significance. An ES of 1 is considered large, 0.5 medium.

[e]FDA-approved for short-term treatment of hyperactive children.

[f]Although haloperidol and chlorpromazine have FDA-approved indications for short-term treatment of hyperactive children; antipsychotics should be a last resort because of the risk of tardive dyskinesia. Newer ones, such as risperidone, olanzapine, and quetiapine, may carry less risk.

[g]The precursors of neurotransmitters are nutrients found in the normal diet. They are included because they are used like drugs in supplemental dosage. Deanol (dimethylaminoethanol [DMAE]) was formerly marketed as Deaner®, but initial FDA approval was withdrawn as "possibly effective."

Not ordinarily used: most minor tranquilizers, benzodiazepines Contraindicated: barbiturates (aggravate hyperactivity; can even cause it)

TCA, tricyclic antidepressant; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; ES, effect size, the number of standard déviations different from placebo or from pre-drug measure. It is a measure of clinical significance. An ES of 1 is considered large, 0.5 medium.

TABLE 5.1.1.10

RELATIVE ADVANTAGES AND DISADVANTAGES/SIDE EFFECTS OF ADHD DRUG CLASSES

Drug Class	Advantages	Side Effects, Disadvantages
Stimulants (FDA indication)	Specifically treat ADHD core symptoms of inattention, overactivity, and impulsiveness Largest and most rapid effect on ADHD of any drug class, especially for children Significant benefit in 85–90% of ADHD if two or more tried in succession and titrated carefully Calms comorbid aggression and oppositional defiant behavior Results of given dose seen immediately; relatively easy titration	Appetite, weight loss Sleep disturbance (if taken late in day) Cramps (first few wks) Headaches Mild BP and pulse increase Evening crash "Zombie" appearance (amphetamine look): constricted affect and spontaneity, emotional blunting Depression Tics Hallucinations (skin crawling, visions) Mild growth slowing first 2 yrs (31) Dose for behavior may not be optimal for attention Nuisance of schedule II Rx
Atomoxetine (Strattera®) (FDA indication)	Specifically treats ADHD core symptoms of inattention, overactivity, and impulsiveness FDA indication for ADHD, like stimulants, but not Schedule II Refills by phone Nearly as effective as stimulants (slower onset), better for some; may help stimulant failures Continuous duration of effect Little or no insomniac side effect Can be given any time of day No tic side effect (good choice with comorbid tics) Some benefit for comorbid oppositional defiant symptoms May help comorbid depression Smooth action over time (long pharmacodynamic half-life), cumulative benefit	Appetite, weight loss Gastrointestinal Sx (nausea, vomiting, diarrhea, constipation) Fatigue, dizziness Probable mild growth slowing Allergic reactions In adults: dry mouth, urinary retention, sexual dysfunction Irritating to skin if capsules opened Possibly longer time than stimulants to flush out if adverse effect Slower attainment of full effect than stimulants
Antidepressants Tricyclics, bupropion (Wellbutrin), MAOIs (32), probably newer antidepressants with both serotonin action and dopamine	Treat both ADHD and comorbid depression and anxiety Helps some stimulant nonresponders Third most effective drug class for ADHD (except for SSRIs, which are not very effective) Some patients/families who are prejudiced against stimulants will accept antidepressants May equal stimulant effectiveness for adults	Sedation BP changes (down or up) Dizziness (especially on standing) Dry mouth Cardiac conduction block: TCAs require ECG monitoring in children Constipation, urinary retention (rare in children) Headache (deserves evaluation) Overdose lethal, and sudden deaths at therapeutic dose (DMI) Response delayed, especially bupropion Dietary restrictions

		for MAOIs Not as good as stimulants for attention
α_2-Agonists	Treat both hyperactivity impulsiveness and comorbid tic disorder or comorbid aggression Helps some nonresponders to stimulants and antidepressants Good for those overaroused, possibly with comorbid anxiety May be especially good with comorbid autism	Response delayed Sedation Hypotensive dizziness (especially postural) Dry mouth Rare hallucinations Hypertensive rebound if dose missed Sudden deaths (when used with stimulant) Not as helpful for attention as stimulants
Buspirone	Good for comorbid anxiety and aggression, possibly depression Relatively safe (similar to stimulants) Smooth effect Relatively free of side effects	Possible paradoxical excitation Several weeks needed to see full effect of a given dose; therefore, hard/slow to titrate
Antihistamines (older)	Safe, cheap, over the counter Especially good in patients with possible allergic etiology (but not restricted to those)	Sedation Risk of seizures in high doses Not as effective as stimulants, atomoxetine, or antidepressants: unsatisfactory in many patients
strong>Antipsychotics*	May work when stimulant or atomoxetine does not, especially if stimulant makes worse Good for comorbid anxiety, aggression, tic disorder, or bipolar disorder	Sedation Extrapyramidal side effects Endocrine effects Tardive dyskinesia Paradoxical agitation (akathisia) Weight gain Not specific, generally less effective than stimulants or atomoxetine Riskiest drug, last resort
Anticonvulsants	Good for comorbid mood disorder, aggression, explosiveness, impulsiveness May work when stimulant, atomoxetine, or antidepressant does not	Blood tests for levels and safety monitoring Liver toxicity Blood dyscrasia Sedation or agitation Ataxia

*Although some antipsychotics (haloperidol and chlorpromazine) have an FDA-approved indication, they should not be preferred to unapproved drugs higher on the list unless for a specific reason, such as comorbid bipolar disorder.
TCA, tricyclic antidepressant; MAOI, monoamine oxidase inhibitor; DMI, desipramine; SSRIs, selective serotonin reuptake inhibitors.
Reproduced with permission from Arnold LE: *Contemporary Diagnosis and Management of ADHD.* Newtown, PA: Handbooks in Health Care, 2004.

This brings us to the other side of educational considerations: the education of patient and family (and other caregivers) about ADHD, its symptoms, course, chronicity, treatments, and services available. Some “talking points” for this are listed in Table 5.1.1.11. Referral to a support/advocacy organization, such as

ChADD or ADDA for further peer education may also be useful. There are also numerous explanatory books written for both children and adults, such as *A Family Guide to ADHD* (278). The local support group may have a lending library of these. Such psychoeducation is important in cementing a commitment to enduring treatment for a chronic disorder.

Other Treatments

Treatments other than medication, behavioral treatment, psychoeducation, and special educational services are often called “alternative.” The term “alternative” implies substitution for proven standard treatment. A better name for most alternative treatments would be complementary treatments because they can theoretically be used in combination with standard treatments (analogous to combining two standard treatments such as medication and behavioral treatment), either to enhance benefit of the standard treatment or to address a problem not covered by the standard treatment. For example, mirror feedback might be used to ease evening homework angst at a time when the daytime stimulant is wearing off.

TABLE 5.1.1.11

POINTS FOR EXPLANATION AND CLARIFICATION TO PATIENT AND FAMILY

Talking Point	Reason
Acknowledge what they already know.	Shows respect and attention to their story. Imparts feeling of cognitive familiarity, a base on which to hook the new information.
Give them the current name of the disorder, indicating there are numerous other names.	Defines and clarifies the disorder.
ADHD has many symptoms, and not every patient with ADHD has all of them. Some have partial expressions of the syndrome.	Prevents confusion from having symptoms that are different from those of an acquaintance with ADHD.
Three main symptoms are inattention, hyperactivity, and impulsivity.	Focuses the targets of treatment. Prevents assumption the patient needs to be aggressive.
Other symptoms are frequent and often disabling, though not important for the diagnosis.	Puts all symptoms in perspective.
Symptoms are just excess amounts of normal behavior.	Implies need to control symptoms, not eliminate them.
Symptoms are not the patient’s fault, but the patient can improve with help.	Breaks up the blame game, prevents giving up. Promotes teamwork in fighting ADHD.
ADHD lasts a long time, perhaps a lifetime, although it tends to get better with age.	Prepares for long-term treatment.
Important not to give up or neglect treatment.	Giving up allows secondary problems, dropping farther behind.
Treatment helps prevent secondary problems.	So they don’t just wait for things to get better.
Many different treatments are available, relative advantages/disadvantages, and scientific basis of each.	So they’ll know the options, be involved in choice of treatment, and, therefore, commit to it.

Laser acupuncture	Stimulate foci for calming	Open trial	ES 1.0	2; Controlled tri
EEG biofeedback	Suppress theta, increase beta	Open and randomized nonblind controlled trials	ES > 0.5, $p < 0.05$	3; Sham-contrc trial
EMG biofeedback, relaxation, hypnosis	Lower arousal, muscle tone	Randomized trials with controls	ES 1.0–1.3, $p < 0.01$	0 for hypnosis; for EMG/relaxati cf. med
Meditation	Autonomic effect focused attention	cf. relaxation, wait list ctrl, med	$p < 0.05$	3; Rigorous replication, sha ctrl
Mirror feedback	Improve deficiency in self-focus	Randomized crossover w. and w/o cf. controls	ES 0.5, $p < 0.05$	3; Replication,
Channel-specific perceptual training	Basic readiness skills, focus	Randomized trial with 2 control groups	ES 0.9, $p < 0.01$	3; Controlled T: trials
Vestibular stimulation	Modulate behavior, attention, perception	Open and single-blind trials rotary stimulation	ES 0.4–1.2, p ns–0.001	3; Randomizec sham-contro trials
Cerebellar training	Patterning of behavior, organization of perceptions	Open trials, not well diagnosed, one with waitlist control	$p < 0.05$	1; Controlled tri with compari Tx of equal duration and intensity
Massage	Vagal tone, 5HT, soothing	Single-blind comparison to relaxation	ES med-large $p < 0.05$	3; Replication, better assessment
Antifungal Tx	GI yeast toxin; breach mucosa	No data in ADHD; other placebo trials	(ES 1.1–3; $p < 0.003$)	1; Trials in ADH
Thyroid Tx	Thyroid function affects ADHD Sx	Placebo trial: 5/8 GRTH, 1/9 other	ns. If thyroid function not abnormal	0, if thyroid nor 6, if thyroid abnormal
Deleading	Lead toxicity causes ADHD Sx	Placebo-controlled trial of chelation (= MPH)	ES 0.7–1.6, p. 05–0.001	4, if blood Pb > 2 if Pb < 20; trial
Comprehensive vitamin/mineral supplementation	Correct dietary insufficiency; meet genetic	RCT in adults	ES 0.69, $p = 0.002$	3; Compatible v other treatments; r

special needs	reduce optim dose of medication Needs replicati

[a]Ratings: 0 = not worth considering further (despite, in the case of amino acids, some evidence of shor hypothesis or collateral support or wide clinical experience, needs pilot data; 2 = promising systematic c trial; 3 = promising prospective data (perhaps with random assignment to control or objective/blind mea important control or controlled trial(s) with trends suggesting further exploration; 4 = one significant doub needing replication or multiple positive controlled trials in a treatment not easily blinded; 5 = convincing c evidence but needs further refinement (e.g., define target subgroup) for clinical application; 6 = should b Tx for the appropriate subgroup.

[b]The rating would be 6 for patients showing frank deficiency of vitamins, iron, zinc, or other nutrients.

ES, effect size, Cohen's d (number of standard deviations difference between means): small ES < 0.3; ES = 1.0; p, probability; DB, double-blind; DO, dropout rate; MPH, methylphenidate; RCT, randomized c recommended dietary intake; Sx, symptoms; Tx, treatment; XO, cross-over trial.

Adapted with permission from Arnold, LE: *Contemporary Diagnosis and Management of ADHD.* 3rd ed in Health Care Co., 2004.

Unfortunately, the evidence base for most such treatments is rather thin. For example, the mirror feedback mentioned has only one published small randomized controlled trial, which showed a medium effect compared to the control condition. Some other treatments (149,157,279–281) are supported only by open trials or clinical observation. The reported improvement for some is likely due to nonspecific effects (placebo, maturation, history, regression to the mean). However, others have multiple placebo-controlled trials showing medium to large effects, often for only a small subgroup. Objective assessment of the evidence is complicated by unsubstantiated claims and assumptions made by some advocates of such treatments. The task of understanding them is discouraging enough to induce many busy practitioners to discard the lot as not worth the effort. Nevertheless, impatient rejection of such treatments without examining the evidence is as unscientific as uncritical acceptance. Most important, surveys indicate that a high proportion of patients use such treatments on their own, without professional guidance. Therefore, it behooves the practitioner to know enough about them and their varying evidence bases to advise and guide the families about likelihood of benefit, possible risks, and risk–benefit ratio. (Summaries of evidence for various treatments may be found in the references for Table 5.1.1.12.)

The following points may be useful in guiding families:

1. The easier, cheaper, and safer a treatment is, the less evidence is needed to justify an individual trial, especially if it can be done along with a proven standard treatment. Risky treatments need controlled convincing evidence. Difficult or expensive treatments risk diverting family emotional and financial resources from better proven treatments.
2. Look for controlled trials in well-characterized samples, not anecdotes or testimonials. A major flaw in many published alternative/complementary treatment studies is lack of diagnostic rigor, second only to lack of controls.
3. Herbs are crude drugs (if they work) and can have interactions with other drugs,

either prescription or over the counter. Most families do not realize this because herbs are peddled as "nutritional" and "natural" or "dietary supplements," which most people mistakenly interpret as perfectly safe. Some herbs, with further research, may indeed be found useful for treatment of ADHD, and may contain psychoactive chemicals, such as nicotine from tobacco leaf, that can be refined into useful drugs. For now, the unknown risk appears to exceed any proven benefit. To prevent herb–drug interactions, physicians should inquire about herbs or "dietary" supplements containing herbs before prescribing, and explain the risk.

4. Remember that delay of proven treatment is a risk, varying in seriousness with the urgency of the presenting clinical picture. This is a consideration where the family wishes to substitute an alternative they have heard about for standard treatment.
5. Rather than merely advising against an unproven treatment, it is more useful to discuss what is known about it and help the family reach a considered decision. If the treatment is easy, cheap, and safe, there would seem little harm in accepting a trial and providing some guidance about how to monitor the results (baseline and follow-up measures, log of observed behavior), and the clinician's open-mindedness may help the family accept the recommended standard treatment.
6. When any treatment (including standard treatments) is tried, it is important to document the effect. Some rating scale or behavior count at baseline can be repeated periodically to see if there is reasonable progress. If there is, a trial of stopping the treatment can test whether the benefit was nonspecific (e.g., placebo benefit) or specific to the treatment. Lack of progress after a reasonable trial would seem prima facie evidence that it is not working for this patient.

Each family must find its own palatable and effective combination of treatment with professional guidance. The 36-month results of the Multimodal Treatment Study of children with ADHD (282) demonstrated that with treatment, symptoms abate significantly by the end of a year for most patients, and at 3 years continue to be significantly better than baseline, even though a substantial minority were able to terminate treatment by that time.

CHAPTER 5.1.2 ■ OPPOSITIONAL DEFIANT AND CONDUCT DISORDERS

JOSEPH M. REY, GARRY WALTER, AND CESAR A. SOUTULLO

Children and adolescent who are sullen, argumentative, uncooperative, miss school, and lie about their whereabouts, refuse to adhere to curfews, steal money from home, etc. represent one of the largest group of patients seen in child and adolescent mental health settings; they are usually labeled as suffering from oppositional defiant disorder (ODD), conduct disorder (CD), or disruptive behavior disorder (DBD). The last term was often used to include also children with attention-deficit hyperactivity disorder (ADHD). However, in this chapter, the term DBD refers only to young people with ODD or CD. The cost of DBDs to the individuals themselves, their families, and society is high (1,2).

Individuals with ODD and CD share many characteristics. For example, their conduct is socially unacceptable, they cause disruption or distress to others more than to themselves (i.e., they "externalize" their problems), and they are more likely to be male and to find it difficult to learn from experience. Yet, they also differ widely from one another: they may be aggressive or not, break the law or not, feel guilt and empathy or not, may be sensation-seeking or not. Although ODD and CD represent well-characterized, reliable behavioral syndromes, they do not fit easily into a traditional "illness" model because children with these problems are heterogeneous in relation to etiology, natural history, response to treatment, and outcome. This is similar to what happens with heart disease, where multiple factors contribute to the pathology and other illness characteristics, but the construct has heuristic value. Because of their heterogeneity, the usefulness of a diagnosis of ODD or CD for treatment planning is limited. For example, "an 8-year old child who initiates fights, bullies others, and hurts animals and a 16-year-old adolescent who sets fires, steals from others' homes and is truant from school would both receive a diagnosis of CD" despite having a very different picture and probably requiring a different management (3). An emphasis on identifying each child's problems and modifying the individual risk factors is likely to be the best way of managing these disorders, as is the case with heart disease.

ODD and CD are described together here to highlight their similarities and differences and to avoid unnecessary repetitions. The content of this chapter overlaps and should be read in conjunction with topics discussed in other parts of the book.

CLASSIFICATION

DSM-5 and ICD-11

DSM-5 (4) incorporated only minor modifications to the DBDs—criteria for diagnosis remaining the same as in DSM-IV—but are grouped differently. In DSM-5, ODD and CD have been placed in the chapter "Disruptive, Impulse-Control, and Conduct Disorders" together with conditions such as intermittent explosive disorder, pyromania, kleptomania, and antisocial personality disorder (ASPD). This grouping seems to assume that these conditions—involving problems with self-control that impinge on others—are part of a continuum with ODD at one end and ASPD at the other. In the provisional draft of ICD-11 (5), impulse control disorders other than ODD and CD are listed in a separate chapter (see Table 5.1.2.1). At this stage, ICD-11 is not expected to provide diagnostic criteria but model descriptions of the disorders.

While criteria for ODD have not been changed, in DSM-5 symptoms are grouped into three types: angry/irritable mood, argumentative/defiant behavior, and vindictiveness—highlighting the emotional and behavioral aspects of the syndrome (Table 5.1.2.2). In DSM-IV, a diagnosis of CD pre-empted a diagnosis of ODD; this exclusion has been removed in DSM-5. That is, individuals can be diagnosed as suffering from both ODD and CD concurrently. Criteria for CD remain the same as in DSM-IV (6) but the specifier "with limited prosocial emotions" has been added in DSM-5. This specifier applies to young people with CD who show a callous and unemotional interpersonal style across multiple settings and relationships (see below).

The clustering of ODD symptoms in DSM-5 in a subgroup of anger/irritability and another of argumentativeness/defiance is supported by studies showing that these behaviors tend to occur together and predicted, respectively, internalizing and externalizing behavior later on (7,8).

DSM-III (9) divided CD into four subgroups according to whether children are socialized or undersocialized, and aggressive or nonaggressive (e.g., socialized/aggressive; socialized/nonaggressive). This was changed in DSM-III-R to "solitary type" and "group type." DSM-IV classified CD according to age of onset (childhood- or adolescent-onset type, depending on whether there were symptoms prior to the age of 10 years). DSM-5 retains the same two types and adds the further specifier of "with limited prosocial emotions."

In recent years, there has been a resurgence in interest on the traditionally described as "psychopathic" traits, in the case of young people often referred to with the term "callous–unemotional." These youth are described in DSM-5 as "with limited prosocial emotions." This label defines children and adolescents who show lack of remorse and guilt after doing something wrong, do not care about the negative consequences of their actions, appear cold and uncaring, show no concern for the feelings of others, are undaunted by their poor performance at school, and their emotions appear shallow or insincere. These young people respond poorly to punishment, show lower cortisol levels, seek novel, exciting, and dangerous

activities, are prone to boredom, and have lower trait anxiety than other youth with the same level of conduct problems (4,10).

ICD-10 (11) describes three subtypes of CD: confined to the family context, unsocialized, and socialized. It is not clear what subtypes, if any, will be included in ICD-11.

TABLE 5.1.2.1

COMPARISON BETWEEN DSM-5 AND ICD-11[a] CLASSIFICATION AND DESCRIPTION OF DISRUPTIVE BEHAVIOUR DISORDERS

	DSM-5	ICD-11[a]
Chapter	Disruptive, impulse control and conduct disorders	Disruptive behavior and dissocial disorders
Disorders included	• Oppositional defiant disorder • Conduct disorder • Intermittent explosive disorder • Pyromania • Kleptomania • Antisocial personality disorder • Other specified disruptive, impulse control and conduct disorder	• Oppositional defiant disorder • Conduct–dissocial disorder • Other specified disruptive behavior and dissocial disorders
ODD	• A pattern lasting more than 6 mo of angry or irritable mood, argumentative and defiant behavior, or vindictiveness and exhibited at least with one individual who is not a sibling as manifested by the presence of at least 4 of 9 behaviors in the previous 6 mo (see Table 5.1.2.2) • Associated with distress in the individual or others or results in significant impairment in in functioning	• A pattern lasting more than 6 mo of markedly defiant, disobedient, provocative or spiteful behavior that occurs more frequently than is typically observed in individuals of comparable age and developmental level and that is not restricted to interaction with siblings • Of sufficient severity to result in significant impairment.

CD	• A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms or rules are violated, as manifested by the presence of at least 3 of 15 behaviors in the previous 12 mo (see Table 5.1.2.2).
	• These behaviors results in significant impairment in personal, family, social, or academic functioning
	• Specifiers:
	  • Of childhood- or adolescent-onset
	  • With limited prosocial emotions
		• A repetitive and persistent pattern of behavior in which the basic rights of others or major age-appropriate societal norms, rules, or laws are violated
		• The behavior pattern must be enduring over a significant period of time (e.g., 6 mo or more). Isolated dissocial or criminal acts are not in themselves grounds for the diagnosis.

[a]Beta draft (5). The ICD-11 working definitions are not final, are subject to change, and have not been approved by the WHO.

ODD, oppositional defiant disorder; CD, conduct disorder.

TABLE 5.1.2.2

Behaviors[a] Suggestive of Oppositional Defiant Disorder (ODD) and Conduct Disorder (CD) According to DSM-5[b]

Oppositional Defiant Disorder	Conduct Disorder
Anger/irritability	**Aggressiveness**
1. Losing temper	1. Bullying, threatening or intimidating others
2. Touchy or easily annoyed	2. Initiating physical fights
3. Angry and resentful	3. Has used a weapon
Argumentativeness/Defiance	4. Physically cruel to people
4. Arguing with adults	5. Physically cruel to animals
5. Defying or refusing to comply with adults' requests or rules	6. Stealing while confronting a victim
6. Deliberately annoying people	7. Forcing someone into sexual activity
7. Blaming others for their mistakes or misbehavior	**Destruction of Property**
Vindictiveness	8. Setting fires
8. Spiteful and vindictive	9. Destroying others' property
	Deceitfulness or Theft
	10. Breaking into someone's house, building or car
	11. Lying to obtain goods or favors or to avoid obligations
	12. Stealing without confronting a victim
	Serious Violations of Rules
	13. Staying out at night before age 13 despite parental prohibitions
	14. Running away from home overnight
	15. Truanting from school before age 13

[a]Wording is summarized.

[b]ICD-11 does not envisage including criteria for diagnosis; it plans to provide diagnostic descriptions instead.

Some researchers have emphasized the importance for outcome of overt (characterized by confrontation and fighting) and covert (typified by deception, such as stealing and lying) symptoms (12), which overlaps with the aggressive–nonaggressive distinction. There are data showing that two different types of covert antisocial behavior may exist: property violations (e.g., stealing) and status offenses (truancy, running away). Other scholars suggest that life-course persistent (beginning during childhood and persisting past adolescence) and adolescence limited is a prognostically useful distinction (13), and this has been incorporated in DSM-5.

Comorbidity

The vexatious issue of comorbidity is highly relevant for ODD and CD since both often co-occur with other diagnoses. The most frequent comorbidities are with ADHD (about 10 times more often than expected (14)), major depression (about seven times (14)), and substance abuse (in adolescents, about four times (15)). According to ICD-10, CD is not diagnosed if ADHD is present (it would warrant a diagnosis of hyperkinetic CD), or if CD is associated with emotional disorders (mixed disorder of conduct and emotions). It is not clear yet how ICD-11 will deal with this issue. In similar circumstances, DSM-5 allows multiple diagnoses to be

made (e.g., ODD *and* CD, ODD *and* ADHD, CD *and* major depression). However, a diagnosis of ODD or CD should not be made if symptoms occur exclusively during the course of a psychotic, substance use, depressive, or bipolar disorder, and the young person does not meet criteria for disruptive mood dysregulation disorder.

Reliability

The diagnoses of ODD and CD have acceptable interrater and test–retest reliability, comparable to or better than the reliability of most psychiatric diagnoses in young people (16,17). Agreement varies according to the informant and age of the child, being usually higher when parent or teacher reports or multiple informants are used, for aggressive than nonaggressive behaviors, and in older children or adolescents. Reliability is also higher in clinic than in community samples due to base rate issues. For example, test–retest agreement of CD using the NIMH Diagnostic Interview Schedule for Children Version IV in a clinic sample was $\kappa = 0.70$ for parents as informants, 0.86 for children, and 0.71 when using data from both. The parallel results in a community sample were 0.56, 0.64, and 0.66 (17). Reliability of ODD is lower, in the range of $\kappa = 0.4–0.6$ (16,17).

Validity

Developmental Considerations

Children's prosocial impulses already become apparent in the first year of life, for example, through cooperative interactions and sharing. Learning how to deal with and tolerate frustration are important aspects of the socialization process. A degree of defiance and noncompliance is normal in toddlers, probably reflecting the child's assertiveness and search for autonomy or ignorance of what parents are prepared to tolerate. Notwithstanding this, toddlers' behavior may already be indicative of problems when it is too intense, persistent, or pervasive. However, there are considerable individual variations and distinguishing behaviors that are within the normal range from problematic defiance or noncompliance is difficult at that age. Prosocial behaviors usually increase up to the age of 3 years; a temporary decline then begins to emerge. Defiance and noncompliance, particularly in boys, may also increase about the age of 2 or 3 years.

Males report greater involvement in physical fights (58% of grade 9 students in the United States) than females (43%). Among US students, physical fighting generally decreases with age, from 43% among grade 9 females to 25% in grade 12; the corresponding figures for males being 58% and 42%. There has also been a reduction in reports of involvement in physical fights from 1991 to 2013: a decrease of 43% in grade 9 males and 46% among females (18).

ODD symptoms appear earlier than CD symptoms. Aggressive behavior (hitting, biting, smashing objects) is common in 4 to 8 year olds and decreases with age, although severely aggressive acts typically start after puberty. Covert antisocial actions such as property and status violations (stealing, truancy, running away) increase as children become older, being more prevalent during adolescence. Early adolescence is often associated with an increase in rebellious behavior. Teachers' reports indicate that most oppositional symptoms, such as arguing, screaming, disobedience, and defiance, peak between 8 and 11 years and then decline in frequency.

Stability and Change

Disruptive behaviors are quite prevalent in children but often extinguish as they grow older. However, many data show that CD symptoms are more enduring than changeable (19). Callous–unemotional traits can be identified as early as 2 years of age and are present in about half of the children who meet criteria for CD. It is possible that callus–unemotional traits are largely responsible for the stability of CD, although they can change from childhood to adulthood (they remain in about 20% to 30% of youth) (20,21).

ODD and CD

The relationship between ODD and CD is complex. In some children, ODD symptoms begin in infancy, persist during childhood, and evolve into CD, often after puberty. Other young people show noncompliance and defiance for short periods or do not progress to CD; this may occur more often in females than in males (22). Oppositional behavior is present only at home in some children, while symptoms occur in most settings in others. ODD often starts in the family context and generalizes to other settings over time. Taken together, these and other findings already mentioned suggest that ODD and CD are best considered as distinguishable if highly correlated dimensions of psychopathology at the phenotypic level (23).

Adult Outcomes

The continuity between childhood CD and adult ASPD has long been known (24), so much so that DSM-5 requires evidence of CD symptoms prior to the age of 15 to make a diagnosis of ASPD—implying that ODD, CD, and ASPD are part of a dimension of psychopathology.

Data are mounting showing that childhood DBDs are associated not only with ASPD but with a wide range of other psychiatric disorders in adulthood (e.g., substance abuse, major depression, psychosis), as well as with many adverse outcomes such as suicidal behavior, delinquency, educational difficulties,

unemployment, and teenage pregnancy (25–28). For example, in a cohort studied prospectively, 25% to 60% of adults with any psychiatric diagnosis had a history of CD or ODD (25). The association, which applies equally to males and females (26), reflects not only the already noted stability of disruptive behaviors, but also the fact that childhood DBDs often trigger a chain of events that increase the likelihood of such unfavorable outcomes (e.g., early defiance may lead to harsh parental discipline, aggressiveness, and peer rejection, which may in turn be followed by association with deviant peers, antisocial acts, substance use, conflict with the law, and mental illness). Studies by and large show a dose–response relationship: The higher the number and variety of disruptive behaviors, the worse the adult outcomes. This said, most adolescents with CD do not develop ASPD in adulthood. A large decline in delinquent and antisocial activities is a commonly reported phenomenon in early adulthood (29). It is not clear if this parallels a reduction in DBDs or if their manifestations change with age (e.g., whether behaviors extinguish, mutate into other psychiatric problems, or delinquent acts become more covert). This decline may reflect the existence of a *desisting* adolescent-limited CD—as opposite to a life-course *persistent* (13). Early onset (displaying mostly ODD symptoms), severity, and exposure to risk factors would predict the latter group (29).

Most epidemiologic studies in adults have neglected to examine the prevalence of the so-called childhood-onset disorders. A survey of people older than 18 years in the United States reported a 12-month prevalence of 1% each for ODD and CD (30). Thus, ODD symptoms can persist into adulthood and significantly interfere with functioning, particularly in social or interpersonal contexts (31). Symptoms consistent with ODD can, therefore, be found in adults although it is not clear whether they appear *de novo* or—more likely—are a continuation of childhood problems.

There is less information about what happens to children with ODD who do not develop CD when they grow up. Some data suggest heterotypic continuity between symptoms of irritability (losing temper, being touchy or easily annoyed, angry and resentful) and later internalizing problems, particularly depression, which is not gender specific (32). Chronic irritability during the preschool years is associated with a variety of anxiety, depressive and DBD symptoms, functional impairment, and service use 6 years later (33).

In relation to criminality, individuals with high levels of psychopathic traits are more likely to engage in criminal behavior but individuals engaging in criminal activities do not necessarily have high levels of psychopathic traits. Nevertheless, adolescents with callous–unemotional traits are at a higher risk of violent reoffending earlier than their young offender peers and appear to be more chronic in their adolescent offending (21).

EPIDEMIOLOGY

Prevalence

Estimates of the prevalence of ODD and CD vary depending on the population, diagnostic criteria, instrument used, period considered (point or lifetime), and informant. Recent surveys (mostly using DSM-IV criteria) in several countries have produced reasonably consistent results, summarized in Table 5.1.2.3. Overall, about 3% of children aged 6 to 18 years met criteria for ODD or CD in the previous 3 or 6 months, slightly lower rates than those reported in earlier studies using DSM-III or DSM-III-R criteria (34).

An examination of questionnaire data of 6 to 17 year olds from nine cultures showed that cultural differences had a small effect on delinquent behavior (1%) and aggressive behavior (5%) syndromes (35). ODD and CD are two to three times more prevalent in males than females, though this may vary according to age. Earlier studies suggested that ODD was more prevalent in children (this was incorporated in ICD-10, where diagnosis of ODD is discouraged after the age of 10 years), while CD was more prevalent in adolescents. Epidemiologic data is inconsistent with this view; prevalence across studies is similar in both age groups.

TABLE 5.1.2.3

PREVALENCE (PERCENT) OF OPPOSITIONAL DEFIANT DISORDER (ODD) AND CONDUCT DISORDER (CD) IN SELECTED EPIDEMIOLOGIC STUDIES

	ODD					CD			
Sample	Male	Female	Children	Adolescents	Total	Male	Female	Children	Adol
3,171 Australian children aged 6–17 yrs (95)						4.4	1.6	4.4	2.4
1,420 children from North Carolina aged 9–13 yrs (96)	3.1	2.1	2.0	3.0	2.7	4.2	1.2	2.4	2.7
10,438 British 5–15 yr olds (97)	3.2	1.4	2.6	1.4	2.3	2.1	0.8	0.9	3.3
1,886 children aged 4–17 yrs from Puerto Rico (98)					2.0				
1,251 children aged 7–14 yrs attending school in					3.2				

Brazil (99)								
541 students in Hong Kong (100)	6.9	6.8		6.8		1.9	1.4	1.7
6,150 children aged 7–9 yrs in Norway (101)	4.0	1.3	2.7		2.7			
10,148 US adolescents aged 13–17 yrs (102)				8.3				5.4
1,049 school students aged 6–16 in Spain (103)	6.8	4.3			5.6			

Secular Changes

It has been suggested that children, particularly females, born later in the 20th century show higher rates of antisocial behavior than those born earlier (36). Conversely, changes in diagnostic criteria may have led to a progressive “masculinization” of the disorder over time because aggressive girls use verbal abuse more often than physical fighting (37). This is difficult to verify given the limitations of epidemiologic surveys (e.g., changes in diagnostic criteria over time). Indirect approaches, such as variations in juvenile delinquency rates or arrests, are also hazardous because of legal and law enforcement changes over time.

ETIOLOGY

The literature on etiologic and risk factors for DBDs is voluminous and compelling but rather nonspecific; it makes reference to ODD, CD, aggression, juvenile offending, and disruptive behaviors defined in a variety of ways (e.g., (38–43)). Data specific to ODD are scarce. This is not necessarily a major issue given the nature and heterogeneity of the DBDs. Dodge and Pettit (44) note that the model used to study and treat or prevent heart disease is applicable to disruptive behavior problems. Both are vaguely defined, heterogeneous constructs but with easily identifiable outcomes, such as a myocardial infarction or, in the case of disruptive behaviors, truancy. While the traditional goal in medicine is to identify a cluster of symptoms and then to seek a single causal agent, this is not appropriate for heart disease or DBDs, where a single causal agent does not exist. Multiple risk factors or vulnerabilities contribute to the development of heart disease and DBDs, and their recognition has allowed the implementation of successful preventive interventions.

Inheritance

Heritability of antisocial behavior has been estimated at about 50%, though it is not diagnosis specific (45). It appears that what might be transmitted is a general liability to externalizing disorders although there are also disorder-specific liabilities (e.g., for ADHD). Shared environment may specifically influence CD, highlighting the importance of examining shared environmental variables as processes underlying the comorbidity among ODD and CD (46). Although it needs further corroboration, a study showed that an allele of the neurotransmitter-metabolizing enzyme monoamine oxidase A gene increased the risk for adult antisocial behavior among individuals who had experienced childhood adversity (47).

Risk Factors

Well-known risk factors are listed in Table 5.1.2.4. It is important to emphasize that a large component of the association between risk factors, DBDs, and poor outcomes is probably noncausal. Risk factors include, among others, socioeconomic disadvantage, exposure to family violence and dysfunction, lower IQ, and attentional difficulties (e.g., (26,38–47)).

Interactions between risk factors are complex. First, the accumulation of risk may not only act additively, but also multiplicatively. For example, impulsivity may convey a small risk for a child developing CD, but in combination with other factors (e.g., poor socializing experiences, harsh discipline), the risk for antisocial outcomes becomes quite high. Second, while genes are important, they interact with, and are modified by environmental variables in complex ways (48). Thus, it has been shown that genetic influences are stronger in children from poor families than in those from affluent backgrounds (49), and that heritability of problem behavior is significantly lower in children with very low birth weight in relation to gestational age than in those with a normal birth weight (50). Third, genetic factors influence individuals' choices and shaping of their own environment (48). In this line, active children tend to participate in sports and energetic activities; antisocial individuals are more likely to find problematic partners (assortative mating). Fourth, the same risk factor may have different consequences depending on other circumstances. For example, while parental separation increases the risk of DBDs in the children, it may actually reduce that risk if separation means losing contact with an antisocial father (40).

It is firmly established that CD is more prevalent among disadvantaged families, though this applies to relative deprivation; the risk seems to flow from being worse off than other people in the child's community rather than from the absolute level of poverty (51). An ingenious natural experiment in North Carolina confirmed this but also showed that reducing poverty among native American families resulted in a reduction in behavior problems in their children (52). The mechanisms by which this

occurred do not seem directly monetary, rather higher incomes resulted in more parents working, fewer single parents, fewer demands on parents' time, and ultimately better parental supervision, which probably led to the change.

Neuropsychological Aspects

Low resting heart rate, probably reflecting autonomic under-arousal, is the best replicated biologic correlate of antisocial behavior in children and adolescents, although its meaning is still poorly understood (53). Studies using a range of imaging techniques have enabled speculation about the brain regions that may be involved in ODD and CD. The frontal lobe has been a focus of attention. Thus, it has been suggested that atypical frontal lobe activation, as detected on EEG, is a basis for negative affective style in children with ODD (54). Positron emission tomography has shown violence to be associated with decreased glucose metabolism in the prefrontal cortex (55), and orbitofrontal lobe damage has been linked to impulsive aggression (56). Research has also focused on the role of various neurotransmitters, with serotonin having received most attention; there is a suggested link between aggression and low levels of serotonin in the CNS (e.g., (57)).

"What is striking to people who come into contact with these children (…) are the repeated poor choices that they make. Children with DBDs often act impulsively, with apparently little ability to compute the consequences of their poor behavioral choices. Many of these children desperately want to make better choices but become upset when they find themselves yet again in trouble that they did not see coming. Others may pursue selfish goals but with overly optimistic predictions of the likely outcome of their actions and experience frustrated aggression when things do not work out" (58,59). Interest in the neuropsychological processes in children suffering from DBDs is growing. A better understanding of the information processing abnormalities that characterize their decision-making is needed to devise more effective interventions (58). For example, young people with CD, especially if they are aggressive, tend to misperceive other people's intentions as hostile and threatening more often than their peers, thus responding in an unnecessarily aggressive manner, which they feel is justified (4).

As already highlighted, there is considerable evidence that development of CD is negatively associated with IQ, particularly with the verbal components of psychometric tests, compared with their performance as a whole. Children with ODD and CD appear to have a lower sensitivity to punishment, which may reduce their ability to associate inappropriate behaviors and consequences (the result of impaired fear conditioning, reduced cortisol reactivity to stress, amygdala hyporeactivity to negative stimuli, and altered serotonin and noradrenaline neurotransmission). They also show hyposensitivity to reward, which is mediated by sympathetic nervous system hyporeactivity to incentives, low basal heart rate, orbitofrontal cortex

hyporeactivity to reward, and altered dopamine function. The emotional state associated with these changes may make these young people prone to break rules, delinquency, and substance abuse—risk-taking, sensation-seeking behavior—while impairment in executive functions suggests poorer control of emotions and decision-making (60).

TABLE 5.1.2.4

SUMMARY OF FACTORS ASSOCIATED WITH THE DEVELOPMENT OF DISRUPTIVE BEHAVIOR DISORDERS AND OPPORTUNITIES FOR PREVENTION

Risk Factor	Potential Prevention Interventions
Biologic	
• Genetic • Low birth weight • Antenatal, and perinatal complications • Brain injury, brain disease • Male sex	• Improved antenatal, prenatal, and obstetric care. • Quit smoking and drug treatment programs targeted to intending parents • Programs to reduce domestic violence
Individual	
• Below average IQ • Difficult temperament • Aggressiveness • Impulsivity and hyperactivity • Attentional problems • Language impairment • Reading problems	• Early identification, adequate support and services for families and individuals with intellectual disability • Quality home visiting programs which aim to facilitate attachment and enhance parenting skills • Parent management training programs • Head start-type programs • Early speech and reading remediation programs
Family	
• Parental antisocial behavior or substance use • Domestic violence • Single parent, divorce • Harsh discipline, maltreatment, or neglect • Parent–child conflict • Lack of parental supervision • Excessive parental control • Maternal depression and anxiety • Early motherhood	• Quality home visitation programs • Parent management training programs • Programs to reduce domestic violence • Drug-treatment programs • Child protection initiatives • Early identification and treatment of maternal depression • Prevention of teenage pregnancy • Support programs for teenage mothers
Social and School	
• Poverty • Association with deviant peers/siblings • Rejection by peers • History of victimization or of being bullied • Disorganized, disadvantaged, or high-crime neighborhoods • Dysfunctional or disorganized schools • Intense exposure to media	• Measures to reduce poverty and provide a social safety net • Enhance the quality of schools • School programs to reduce bullying and prevent behavior problems • Initiatives to reduce access to firearms, and gang activities • Programs to reduce school truancy • Initiatives to enhance neighborhood cohesion • Law enforcement initiatives to reduce crime targeted to high-crime areas • Public campaigns to reduce media violence and education about how to monitor and prevent children's exposure to it

violence

DIAGNOSIS

Diagnostic Assessment

An evaluation performed by an experienced clinician based on information from multiple sources and supplemented by questionnaire data should allow making a diagnosis of ODD or CD quite reliably. Given the range of problems shown by children with DBDs, it is important to clarify to all concerned the purpose of the evaluation from the outset. Assessment may be requested by parents, schools, courts, children's lawyers, or social services. The purpose will influence how the assessment is conducted and the tone of the interviews. This may also pose limitations to confidentiality, which should be explained to the relevant parties. Building rapport with and achieving cooperation from these children is often problematic because of their difficulty accepting ownership of their actions and hostility to authority figures. Often they do not see a distinction between mental health professionals, parents, teachers, and police. Thus, noncooperation and resistance to disclose information are to be expected. Because referral is often triggered by a disciplinary or legal crisis after months or, more often, years of discord, clinicians are usually confronted with stressed, angry families who are unable to see anything positive in one another.

Reports from children, parents, or teachers may disagree but these sets of information often complement each other. Since sexual abuse, inconsistent parenting, maternal depression, and parental drug use are not uncommon in these children's backgrounds, these areas need to be explored carefully. Learning as much as possible about the parenting style, parent–child interactions, and the child's strengths and relationships with peers will be valuable when planning and delivering treatment.

Boundaries of the Disorder

The developmental issues noted raise the question of the boundaries between disorder and extremes of normal behavior. ICD-10 states that judgments concerning the presence of ODD/CD should take into account the child's developmental level. Temper tantrums, for example, are a normal part of a 3 year old's development and mere presence would not be grounds for diagnosis. While there is much evidence that children who display symptoms of ODD or CD persistently and intensely are significantly impaired (e.g., (61)), it is also clear that a continuum of symptoms exist and that children with a subsyndromal level of diagnostic criteria can be impaired (62).

Gender and Age

Rather than physical attack, females are more prone to use indirect, verbal, and relational violence such as ostracism and character defamation (63). These behaviors can be difficult to document, are not clearly described as CD symptoms, and may result in underdiagnosis of CD in girls (34).

The lowest age at which a valid diagnosis of ODD or CD can be made is unresolved. For example, ICD-10 states that a violation of other people's civic rights (such as by violent crime) is not within the capacity of most 7 year olds and so it is not a necessary diagnostic criterion for that age group. In most cases, symptoms of ODD begin to appear during the preschool years and a valid diagnosis of ODD or CD may be made in preschoolers (64,65). Conversely, the ICD-10 statement warning about diagnosing ODD after the age of 10 years is without foundation since as many young people qualify for ODD in adolescence as in childhood. Further, even some adults may meet criteria for ODD or CD (30).

Social and Cultural Context

DSM-5 highlights that a diagnosis of CD should be made only when the behavior in question is symptomatic of an underlying dysfunction within the individual and not simply a reaction to the immediate social or cultural context. This is to circumvent concerns that a diagnosis of CD may at times be misapplied to individuals in particular settings (threatening, impoverished, high crime, war) where patterns of undesirable behavior could be protective. This does not necessarily imply an absence of CD in those settings, it only means that the context in which symptoms occur needs to be taken into consideration. Although the difference appears theoretically difficult, clinicians seem able to make such a distinction in practice (66).

Comorbidity and Differential Diagnosis

Assessment must cover all symptom domains to ensure that comorbid disorders are not overlooked. It is common for parents, teachers, and clinicians to focus on the more obvious and annoying behaviors and neglect mentioning or inquiring about less conspicuous symptoms and disorders, which nevertheless may be important for treatment and prognosis. As noted, the most frequent are ADHD, mood disorders, and in adolescents, substance misuse. Conditions such as anxiety disorders, tic disorders, specific developmental and learning disorders, autism spectrum disorders, and intellectual disability ought to be considered also. Antisocial behavior is not uncommon in the prodromal stage of schizophrenia (67).

It has been suggested that some children with severe impulsivity, hyperactivity,

unstable mood, irritability, defiance, and conduct problems may suffer from bipolar disorder, resulting in a higher prevalence of bipolar disorder in this age group. The association between DBDs and bipolar disorder in prepubertal children—important for its therapeutic implications—has received much attention and created controversy at the turn of the 21st century, leading to the introduction in DSM-5 of a new diagnosis—*disruptive mood dysregulation disorder*—to describe primary school-age children with severe and chronic negative mood and temper outbursts. There is considerable symptom overlap between ODD and disruptive mood dysregulation disorder but, according to DSM-5, the latter and not ODD should be diagnosed when symptoms are particularly severe and negative mood predominates. The validity of this condition is still questioned; it may represent an extreme form of ODD (68).

A diagnosis of ODD should not be made when defiance, grouchiness, and noncompliance occur only in the course of *major depression* or if ODD symptoms appear when parents try to force anxious children, for example, with a phobia, to confront their fears. Ignoring ODD symptoms when making a diagnosis of depression or ADHD may also occur. ODD may be present if the child has shown symptoms of defiance, temper tantrums, etc. prior to the onset of the other disorder or if oppositionality persists after symptoms of the comorbid condition have lessened.

The possibility of *intermittent explosive disorder* should be considered also. This condition is characterized by impulsive, unpremeditated outbursts of anger and aggression. Such aggressive episodes are uncommon in ODD, while they differ from those in CD in that children with explosive disorder do not seek an ulterior benefit and nonaggressive symptoms of CD (e.g., lying, truancy) are absent.

The existence of intellectual disability creates significant problems when diagnosing DBDs. A diagnosis of ODD is made in individuals with developmental disability only if oppositionality is markedly greater than that observed in youth with similar IQ. Aggressive behavior in intellectually disabled young people is common and often results in placement in residential programs. When present, CD behaviors tend to persist over time, particularly in males, and a comorbid diagnosis of CD would be justified in these cases.

Clinical Assessment

Questionnaires and checklists provide quantifiable data, reliably supplement information obtained at interview, and are useful to measure progress and outcome. Besides general questionnaires such as the Child Behavior Checklist (69), a variety of specific rating scales are available (70), including the Eyberg Child Behavior Inventory (71), the New York Teacher Rating Scale for Disruptive and Antisocial Behavior (72), and the Home and School Situations Questionnaire (73). A comprehensive list of instruments to assist in the diagnosis of ODD can be found here (74).

Psychometric and educational assessment is often useful as part of the initial evaluation; it should be performed when children show difficulties at school or if learning problems are suspected. A careful medical history and review of systems is mandatory in all cases. Routine biochemical, EEG, or radiologic investigations are unnecessary, with the exception of urine drug screen in adolescents (75). Laboratory investigations should be conducted when the clinician uncovers symptoms suggestive of a physical illness (e.g., epilepsy), or for sexually transmitted diseases when sexual abuse has occurred, or there is suspicion of unprotected sexual activity.

TREATMENT

In practice, children with DBDs are treated with a variety of psychological, behavioral, or pharmacologic approaches, alone or in combination, targeting the child and/or the family. Professionals largely believe that therapy is of limited effectiveness in the patients with CD typically seen in mental health settings (more chronic, more disturbed, and usually with comorbid conditions). While there have been considerable advances in the last 25 years, effective treatments are few and no great breakthroughs have occurred. Moreover, treatment research, though vast, is hampered by poor definition of target symptoms, mixed populations, small sample sizes, and poor randomization and blinding, among other limitations. Few trials specifically focus on participants with ODD or CD and it is often difficult to translate findings to the complex circumstances of individual patients. This is compounded by psychosocial treatments being less efficacious when delivered in the average clinic than in academic research settings.

General principles to keep in mind when treating these disorders are (74,76,77):

- DBDs tend to be chronic conditions, more similar to heart disease than pneumonia, and treatment should be tailored accordingly.
- Most guidelines concur that structured psychosocial and behavioral interventions should be the first line of treatment for ODD and CD, and should be continued even if medications are subsequently initiated.
- Treatment is more likely to be effective when administered early in the course of the disorder. Typically, maladaptive behaviors are continually reinforced; over time, negative perceptions, emotions, and patterns of relating become deeper and more entrenched. Once CD is established, it becomes more resistant to intervention.
- Treatment should involve the parents. In almost all instances, improving parenting skills and parent–child interactions are core goals.
- Comorbid conditions (ADHD, depression) ought to be identified and, if appropriate, treated.
- Parental depression, psychosis, or substance abuse should also be noted and treated.

- It is very useful to ascertain children's and families' strengths and build on them in addition to focusing on their problems.
- Dealing with the stress, anger, and hopelessness that many of these families experience and achieving some calm and control is often a necessary initial step.
- The goals of treatment need to be realistic and modified as progress occurs. For example, preventing or minimizing drug use or involvement in delinquent activities in adolescents with CD may be a more appropriate initial step than seeking symptom resolution.
- Because these young people usually show disturbance in a variety of settings (e.g., school, home) and impairment in several aspects of functioning, addressing their multiple needs in the various domains is likely to increase effectiveness (multimodal treatment).
- Association with deviant peers is a well-established factor that increases the likelihood of conduct problems, delinquency, and drug use, particularly in adolescence. A goal should be to enhance participation in activities with well-functioning peers.
- In the case of ODD, the main goal of treatment is to increase compliance and reduce conflict. Therefore, the treatment plan should include ways of helping the young person become more cooperative, less argumentative, and be better accepted by peers, often in a family therapy context.
- Medication should not be offered for the routine management of ODD or CD. In cases of severe aggressive behavior that has not responded to psychosocial interventions, the use of risperidone can be considered in the short term and with the appropriate precautions (e.g., metabolic syndrome monitoring).

Emergencies

Presentation of young people with DBDs to emergency services is not uncommon. For example, 16% of all the child and adolescent presentations to a psychiatric emergency service in Albany, NY, between 1990 and 1995 were due to DBDs (78). Emergencies usually occur following conflict, legal, or disciplinary crises that result in the child losing control and becoming aggressive toward the self, others, or property. Differentiating DBDs from other psychiatric problems in the emergency room is reasonably straightforward, but establishing whether ODD or CD is the more appropriate diagnosis is harder because a comprehensive evaluation is often difficult in that context. Children with DBDs who present to emergency services tend to have more severe disorders, more aggression, more comorbid conditions, and fewer family and social supports than those without DBDs. Police or mobile psychiatric services involvement is often required. Some of the management principles to be followed in these cases are (79):

- Crisis intervention strategies should be employed before resorting to the use of

medication to control behavior.

- Physical and mechanical restraints and locked seclusion should be used only as a last resort, when all other approaches have failed.
- The choice to use emergency ("stat" or "p.r.n.") pharmacologic management should correspond to the risk for potential injury.
- Emergency staff should be aware of the risks and side effects of acute sedation and follow the appropriate protocols.
- When antipsychotic "p.r.n." or "stat" medications are used several times per day to manage agitation or aggression, clinicians should re-evaluate the diagnosis and the adequacy of behavioral and environmental interventions and then readjust the treatment plan and medication regimen. In most cases, physicians should consider using standing antipsychotic medications rather than frequent "stat" medications.

Acute situations similar to the ones seen in emergency settings also occur during inpatient treatment or in institutions. In these settings, crises usually build up over days or hours and can often be predicted. While their management follows the principles listed above, clinicians working in these services need to be skilled in detecting the early symptoms of loss of control and preventing the crisis.

Psychosocial Treatments

Psychosocial interventions that include a parent component, either alone or in combination with other treatments, are likely to be more effective at reducing disruptive behaviors than those that include only a child component (77).

Parent Management Training

Parent management training (PMT) is based on the principles of operant conditioning and social learning theory. In PMT, parents are encouraged to use positive reinforcement, to adopt more effective discipline strategies, and to learn how to negotiate with their children (for a review, see Chapter "6.2.4" in this textbook and (80)).

PMT has been the most extensively researched therapy in this field. It has the potential to produce improvements in child behavior to within the nonclinical range at home and, sometimes, at school. Further, these effects can be maintained, together with indirect improvement in other areas such as sibling behavior, maternal psychopathology, marital satisfaction, and family cohesion (81). Key limitations of PMT include the substantial number of parents who do not complete the program, their frequent ineffectiveness in the most dysfunctional families, and that it has been targeted to younger children.

Multimodal Interventions

Given the variety of symptom and impairment domains, it is thought that multimodal interventions may optimize the chances of success. For example, PMT alone often does not generalize to the school context, and antisocial behavior at school is a predictor of poor outcomes. Also, PMT does not necessarily influence the child's capacity to make friends, when having well-functioning friends is a protective factor. Hence, adding to PMT a component that addresses the child's problem-solving abilities or a teacher-training element may enhance efficacy (82). This multimodal approach has been shown to produce better results than PMT alone (83). Examples of multimodal programs are Multisystemic Therapy (MST) and Families and Schools Together (FAST Track). The former predominantly targets adolescents with severe conduct problems and delinquency, while the latter focuses on conduct disordered children starting school.

MST (see Chapter "6.2.7") also draws on a range of interventions, is home-based, goal-oriented and intensive—it provides therapy 7 days a week for about 4 months (84). A meta-analysis reported that MST is moderately effective in reducing offending, but this appears to be very dependent on the skills of the treatment team (effect sizes ranging from 0.26 to 0.81) (85). MST is resource intensive and there are doubts about its cost-effectiveness (86).

Therapeutic foster care is another multimodal approach in which adolescents are placed with specially trained, intensely supervised foster parents who are supported by a team. There is some evidence this reduces these youths' criminal activities (82).

Evidence for the effectiveness of wilderness programs, boot camps, and other residential treatments is conflicting and studies are of poor quality. A concern about these interventions is that they provide opportunities to associate and identify with deviant peers, and that gains may not generalize outside the treatment setting.

Individual Interventions

Problem-solving skills training is the best studied and it results in a clinically significant improvement (87). In this therapy, children are taught to understand interpersonal problems and find adaptive solutions using various techniques including games, structured activities, stories, modeling, role play, and reinforcement. Studies have also demonstrated at least modest benefits for other individual interventions. A review of 82 controlled trials found that individual assertiveness training, anger control/stress inoculation, and rational emotive therapy were "probably efficacious" (at least two studies showed the treatment to be better than a control condition) (87). Child CBT-based interventions showed a small-to-moderate effect in decreasing antisocial behavior (88).

Pharmacotherapy

Medication is *not* a mainstay of treatment of ODD and CD, and research in this area suffers from most of the shortcomings already noted (77). Psychotropic drugs may be used for the treatment of ODD or CD symptoms if psychosocial and educational interventions have failed and as a part of a comprehensive management plan, although medication is often used for those individuals who have coexisting conditions, such as ADHD, and in emergency situations.

Some principles should be followed when prescribing medication for DBDs besides those already highlighted in the section on emergencies, including (79):

- The dosing strategy of "start low, go slow, taper slowly" should be followed, particularly when using antipsychotic drugs.
- Caution and careful monitoring should be exercised when prescribing stimulants to adolescents with CD, given the high rate of substance misuse in this population.
- Adherence, side effects, and drug interactions should be monitored routinely and systematically. In particular, it is important to ascertain whether patients are concurrently using psychoactive substances or complementary therapies that may interact with prescribed drugs.
- Before switching, augmenting, combining, or discontinuing medications because of a lack of response, it should be ensured that patients have received an adequate trial (dose and duration) as well as psychosocial interventions.
- Polypharmacy should be avoided whenever possible.

Psychostimulants are effective in children with ADHD with significant symptoms of oppositional behavior, conduct problems, or aggression. Treatment with atomoxetine, guanfacine, and clonidine may also provide some lesser symptom relief (89). There is evidence to support the efficacy of risperidone for the treatment of aggressive behavior (90).

Antipsychotic drugs have often been prescribed to manage disruptive behavior in individuals with intellectual disability. Controlled trials suggest these medications, particularly risperidone, are beneficial in this population, at least in the short term (91).

PREVENTION

There is no reason to believe the incidence of DBDs cannot be reduced, since that has been achieved with other scourges such as heart disease, but doing so will require a concerted effort and substantial resources. Child and adolescent mental health professionals have a critical role in educating the community and political leaders on the advantages of prevention over treatment and retribution,

notwithstanding that treatment and law enforcement are important also. Reducing DBDs is one of the challenges for child mental health in the 21st century. Yet simply addressing conduct problems without tackling the social, family, and individual factors associated with these conditions will lead to disappointment. Little may be achieved in communities that fail to protect the disadvantaged and to ensure that all its citizens, particularly women and families with children, are treated with dignity and afforded access to a minimum of resources and life opportunities, as well as having developmental difficulties such as attention and learning problems addressed. Schools can play a key role in this endeavor (92).

Table 5.1.2.3 lists some of the opportunities for prevention and the range of potential interventions. Many prevention programs already exist (93), often implemented *ad hoc* and without much data about their effectiveness; finding that evidence should be a priority for research. Home visitation is one of the most widespread, though with many variations. Evaluations show that home visitation is no silver bullet, but results of the better programs are encouraging. Participation can improve children's cognitive, social, and linguistic development, and reduce child maltreatment and behavioral problems (94).

Most of the therapies used to treat DBDs can be adapted for prevention purposes. For example, there are packages based on PMT principles, such as Triple-P (80), designed for use at several levels: (i) in broad community education (e.g., through media campaigns); (ii) for children at risk in a group format; (iii) for children with a full-blown syndrome in group or individual format. There is limited data on the effectiveness of these programs outside preschool or early primary school-age children.

CHAPTER 5.1.3 ■ AGGRESSION IN CHILDREN: AN INTEGRATIVE APPROACH

JOSEPH C. BLADER AND DANIEL F. CONNOR

INTRODUCTION

Aggressive and Prosocial Behavior

A central goal of every human community is the mitigation of aggression between its members. From the earliest writings, most reflections on human interactions suggest an intrinsic capacity for aggression and brutality (1). Natural drives to acquire resources, to protect those resources and personal safety, and to enhance and defend one's status cause antagonisms that humans, like other animals, resolve through force. Social order demands less destructive alternatives to violence, and moral development and social organization strive to suppress such behavior. Thomas Hobbes (1588–1679) memorably summarized this viewpoint by showing how human communities would not advance very much if we lived in fear of one another (2):

> … In such condition there is no place for Industry because the fruit thereof is uncertain … no commodious Building; … no Arts; no Letters; no Society; and which is worst of all, continuall feare, and danger of violent death; And the life of man, solitary, poore, nasty, brutish, and short.

When Charles Darwin considered these issues within a biologic framework some 200 years later, these predecessors who depicted life as a struggle for existence influenced his work (3). Natural selection involves competition for the resources that are essential to survival and successful reproduction. Scarcity of these resources means that some creatures inevitably deprive others within their species of access to them, often through aggressive behavior. However, Darwin also devoted much attention to the adaptive benefits of the "social instincts," such as sympathy, cooperation, altruism, and the desire to maintain the approval of one's group, which exert an equally natural countervailing force on intraspecific aggression. After all, when danger is at hand humans tend to seek safety in one another's company. Potential procreative partners may also favor these characteristics, accelerating their proliferation through the process of sexual selection (4).

As man is a social animal, it is almost certain that he would inherit a tendency to be faithful to his comrades, and obedient to the leader of his tribe; for these qualities are common to most social animals. He would consequently possess some capacity for self-command. He would from an inherited tendency be willing to defend, in concert with others, his fellow men; and would be ready to aid them in any way,

which did not too greatly interfere with his own welfare or his own strong desires (5).

Since then, behavioral research has supported the overall view that a combination of affective, cognitive, and social factors inhibits the majority of people from harming others most of the time (6,7). We also know a fair amount about when social factors could lose their potency to inhibit aggressive behavior, even in the absence of psychopathology. For instance, aggressive behavior becomes more likely when a potential target belongs to a different social grouping; when one perceives another person as threatening; when one believes that others will approve of or encourage aggressive acts; or, when one believes that the benefits of aggression will exceed its probable cost.

Because many psychiatric disorders have the potential to disrupt cognitive, affective, and behavioral processes that ordinarily inhibit aggressive and other harmful behaviors, these behaviors often arise as a highly disconcerting complication. High negative emotionality may predispose to a low threshold for anger or frustration, so that one reacts forcefully to situations others would find only mildly bothersome. Distorted cognitive processes may lead to unwarranted alarm about environmental threats, to feeling impelled by some force to hurt others, or to erroneous beliefs about entitlement to impose one's will on others. High anxiety may trigger avoidance or escape behaviors that can injure others who get in the way. Inadequate impulse control can disrupt response selection so that aggression has precedence over alternatives. Abnormal development may impair the acquisition of coping behaviors and self-regulatory capabilities that ordinarily suppress dyscontrolled outbursts. A diminished capacity for empathy removes an important restraining factor whereby cues that show the distress of others can reverberate uncomfortably within ourselves.

Certain experiential factors can contribute to persistent aggression and therefore have psychiatric significance. Early severe maltreatment may disrupt the development of empathy. Socialization that promotes violence and threats as vehicles for self-preservation may lead to aggression that persists even in new social contexts that disapprove of such behavior.

Aggressive behavior is therefore an important concern for all mental health professions. Because persistent aggressive behavior most often originates in childhood, and is in itself a frequent reason for which youth obtain psychiatric care, it is especially significant for the practice of child and adolescent psychiatry. Aggressive behavior among school-age children confers high risk for unfavorable outcomes not only during youth but also throughout later life, including early mortality (8–12).

AGGRESSION AND VICTIMIZATION AMONG YOUTH

Community- and Clinic-Based Estimates

Physically aggressive behavior among preschoolers is common but diminishes upon school entry and during the elementary school years. Tremblay et al. (13) found that only a minority (28%) of 3 year olds were said to display little or no aggression. Parent reports indicate that 27% of 3-year-old boys hit, push, or trip others. The comparable rate for girls is 19%. Parents reported "modest aggression" for 58% with equal gender representation (13). Parents reported quite high aggressive behavior among 14%, of whom 57% were male.

In elementary school samples, larger gender differences emerge for "starts fights," with parent reports indicate that fighting is present among about 12% of boys and 6% of girls (14). However, the prevalence of "bullies, threatens, or intimidates" is relatively similar between genders (boys 13%, girls 10%).

Several longitudinal studies have tracked teacher-reported conduct problems through elementary school. Some also had initial assessments from infancy and some had follow-ups through young adulthood. Data from six of these studies found that 8% of boys consistently obtain the highest physical aggression ratings (15). Stability in teachers' ratings of aggressive behavior across many school years is even more striking than the continuity of parent report, because teachers and classmates change annually for most children.

Aggressive behavior is among the most prevalent chief complaints for youth seen in inpatient, outpatient, and residential treatment services. Among preadolescents, aggressive dyscontrol may be the most frequent reason for treatment in specialty mental health services. By adolescence, rising prevalence of mood disorders and self-injurious behavior, particularly among females, eclipses aggressive behavior as a chief complaint. However, new-onset aggressive behavior among girls in early to middle adolescence seems rather frequent, and in clinical samples may be an associated feature of depressive disorders (16). Therefore, despite a shift from "externalizing" to "internalizing" diagnoses with age, aggression may remain a formidable concern.

The majority of youngsters who fight seem to do so in some settings and not others. Aggressive behavior at home only is especially common: about half of boys who fight show physical aggression within the family exclusively. Only 20% were reported to display physical aggression at both home and school (17).

CHARACTERIZING AND SUBTYPING AGGRESSION

The prevailing approach to distinguishing types of aggressive behavior focuses on whether its motivation is mainly (a) to repel a perceived threat or source of frustration, or (b) to acquire something desirable. The former defines *reactive, affective, frustrative, impulsive,* or *defensive* aggression. The latter is associated

with terms like *proactive* or *instrumental aggression.* In general, psychometric and psychobiologic evidence supports such a distinction between these behaviors (18–20). As an approach to categorizing *people,* rather than behaviors, it may have some shortcomings, since many individuals display aggressive behaviors characteristic of both types at various times, and the correlations between them are high (21–25).

Impulsive, Affective, or Reactive Aggression

Affective or impulsive aggression refers to dyscontrolled reactions, which have the potential or the intent to hurt others or oneself, occur upon exposure to events perceived as noxious. The provocations are usually things that one might agree are annoyances, but within a level of intensity that most other children handle with composure. Triggers may appear quite trivial, such as not getting the right cereal for breakfast. Directions to comply with an adult request or the need to end a preferred activity to transition to something else are very frequent antecedents to full-blown rage episodes. Hitting, kicking, destruction of property, and self-abusive behavior are common. A verbal onslaught of screaming, vulgarity, threats, and hurtful insults are themselves very disturbing, even without physical contact. Since the behavior is most often reactive and nearly instantaneous, it tends to be overt and unplanned. These events can also show a self-defeating character. Youngsters in their explosive rage may end up hurting themselves by, for instance, punching walls or glass, damaging their own possessions, or escalating when it should be obvious, that doing so only makes matters worse. They may attack people much larger and stronger than themselves. A few children calm down when placated, but it is also common for these outbursts, once kindled, to have to run their course before the child regains control.

Children with these difficulties typically meet criteria for oppositional defiant disorder (ODD), since its symptoms include frequent loss of temper, anger, susceptibility to slight provocation, and argumentativeness. This pattern of behavior can also contribute to diagnosis of conduct disorder, usually with childhood onset, when it includes threats, fighting, and destruction of property.

Rageful outbursts are the cardinal symptom of disruptive mood dysregulation disorder (DMDD). DSM-5 introduced DMDD as a mood disorder to designate persistent irritability, and better distinguish it from other disorders in which irritability can be prominent but that is typically episodic (e.g., bipolar disorder, major depressive disorder). The DMDD diagnosis therefore requires that one’s prevailing mood in between rageful outbursts is irritable or angry. However, only a minority of youth with significant reactive aggression also show abnormalities of mood when they are not acutely distressed (26,27).

Proactive, Instrumental, or Appetitive Aggression

Proactive or instrumental aggression includes assaultive or coercive behavior purposefully used to achieve a goal such as material goods or social status. Willful property destruction is also included by some. Descriptions of proactive/instrumental aggression sometimes liken it to hunting, but for many species predation and intraspecific aggression have different underpinnings and phenomenology (28). A few features of proactive aggression make plain that the actor is in control. For instance, proactive aggression stops once the goal is achieved or when it becomes clear that it has become unobtainable. Victims are chosen to make success likely. The aggressor may take protective measures to avoid getting hurt and evasive action to avoid apprehension. While planning and premeditation are certainly consistent with proactive aggressive behavior, it is probably not a requirement. A number of "acquisitive" violent acts, such as certain robberies and sexual assaults, are often opportunistic and not necessarily performed with much forethought.

Among youth whose aggressive behavior is principally of the proactive/instrumental type, we can also discriminate two important subgroups.

Adolescent-Onset, Peer-Facilitated Proactive Aggression

First, a group of proactively aggressive youth show adolescent onset of antisocial behavior. Aggressive acts in this context are on the whole less violent, rely on peer encouragement, and seem likely to diminish by adulthood (29–31). However, the boundary between obnoxious pranks and major violations that cause serious injury or damage is fortified by common sense and restraint. The group dynamics of adolescents behaving recklessly do not promote these qualities, often with tragic results. In these situations, a young person may become ensnared by the consequences of delinquent participation. School expulsion, increased wariness of other peers, and involvement with law enforcement or correctional facilities can promote further identification and involvement with delinquent peers, and deflect what had hitherto been a pathway of overall positive adjustment.

Callous–Unemotional ("Psychopathic") Proactive Aggression

Another important subgroup of proactively aggressive youth is profoundly indifferent to the consequences that their misbehavior has upon others. Displays of genuine remorse are rare, and a current descriptor for this group's salient personality features, "callous–unemotional traits," is highly evocative of their lack of empathy, self-centeredness, and shallowness (32). In this respect, they resemble adults with *psychopathic* or *sociopathic* personality traits. When these features are present, the DSM-5 diagnosis of conduct disorder can be accompanied by the specifier, "with limited prosocial emotions." These youth are responsible for a large number of

violent offenses, their aggressive behavior is often persistent and development of these characteristics may be early in childhood (33,34).

Many individuals exhibit *both* the angry overreactivity of affective/impulsive aggression and the deliberate, calculated injury to others characteristic of psychopathy. Indeed, some definitions of psychopathy include both impulsive “hotheadedness” along with the capacity to trample calmly upon the rights of others when it suits one’s purpose.

INFLUENCES ON AGGRESSIVE BEHAVIOR: PSYCHOPATHOLOGY AND PROCESSES

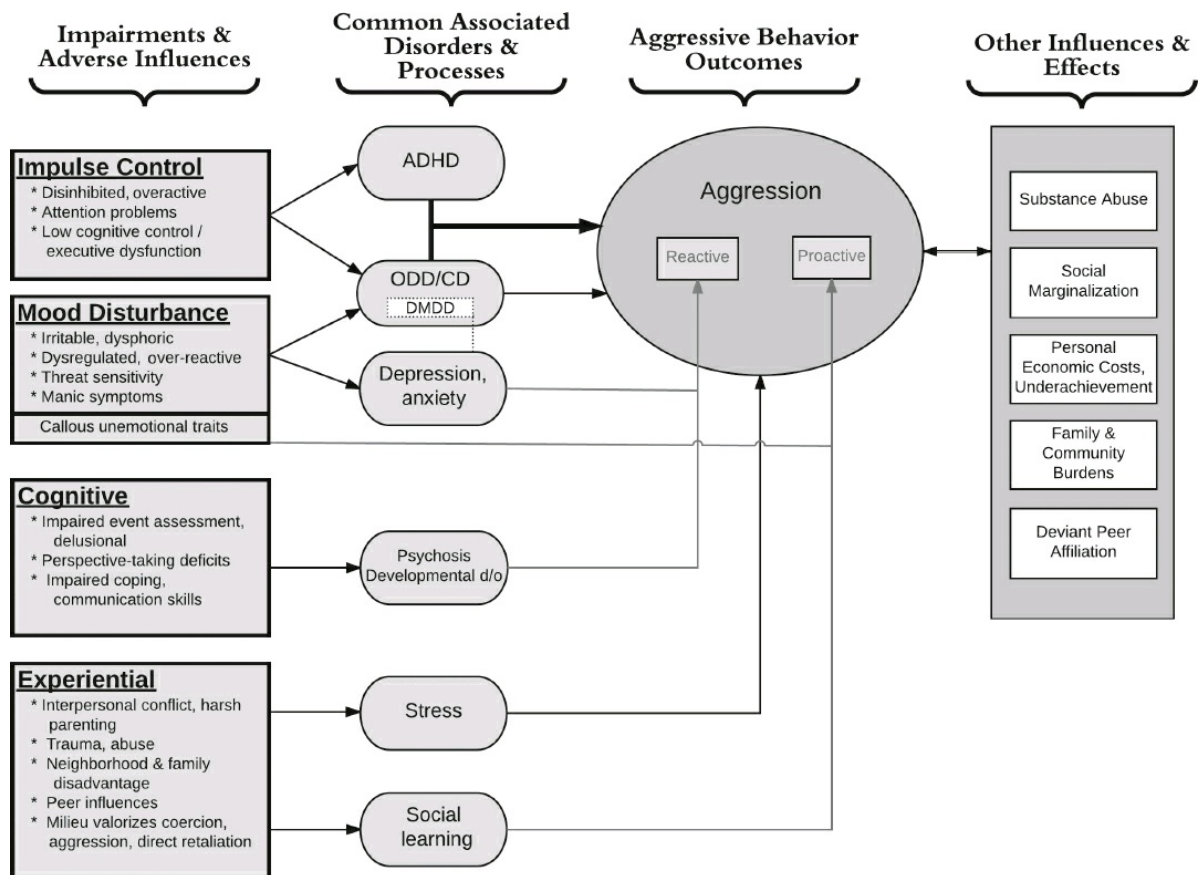
In keeping with the view that diverse forms of psychopathology and unfavorable experiences can lead to aggressive behavior, this section offers a framework that links them (Figure 5.1.3.1). Four broad categories of specific deficits and experiential factors that we distinguish are: impulse control deficits, affective instability, sensory and cognitive abnormalities, and environments that can promote antisocial behavior. Linkages on the left acknowledge the frequent co-occurrence and interdependence of these factors. To the right are several psychiatric disorders and psychosocial processes to which these factors often integral, and that in turn constitute the “psychopathologic context” for aggressive behavior problems in youth. Finally, severely disruptive behavior itself has sequelae that can abate (e.g., interventions) or increase (e.g., social marginalization) persistence and impairments; some of these “impact outcomes” appear on the far right.


FIGURE 5.1.3.1. Influences on the development of aggressive behavior. ADHD, attention-deficit/hyperactivity disorder; ODD, oppositional defiant disorder; CD, conduct disorder; DMDD, disruptive mood dysregulation disorder.

Impulse Control Deficits

Generalized problems with situational awareness and self-control are strongly associated with aggressive behavior (35–37). These problems are "generalized" because affected children often show undercontrol of many functions in numerous settings. These include weak self-restraint of conduct and activity level that often biases action toward disproportionately physical and disruptive responses to minimal provocation, and low effortful cognitive control over one's behavior (e.g., sustaining attention, problem-solving, verbal mediation of conflicts, perspective taking), that make willful selection of alternative responses problematic. Dimensional measures of impulsivity correlate with aggression and self-harming behavior (38,39). Early hyperactivity predicts subsequent aggression (40,41) and, in tandem with early aggressive conduct problems, strongly predisposes to persistent antisocial behavior (42).

These predisposing factors toward behavioral volatility and aggression are prominent in youth diagnosed with attention-deficit/hyperactivity disorder (ADHD). Self-regulation of affect, while not currently part of ADHD's criteria, is often regarded as practically intrinsic to at least some presentations of ADHD (43,44), and

ADHD is ubiquitous among youth with high negative emotional reactivity (45–47).

Although we emphasize ADHD because of its prevalence among aggressive youth, problems with impulsiveness that develop later in life, can also contribute to the onset of aggressive behavior. Impaired self-control can occur in several psychiatric disorders discussed below that often develop in adolescence (such as bipolar disorder, psychosis, and chronic substance abuse), as well as traumatic brain injury (48,49).

Impairments of Mood, Affect Reactivity, and Anxiety

Negative Affect, Mood Disorders

Evidence from several sources implicates affect disturbances in aggression and other early-onset disruptive behaviors. The correlation between negative affective features (e.g., irritability, lability, anger, dysphoria, frustrability) and disruptive behavior is well established (50–52). Unconsolability, low adaptability, and irritability predict subsequent aggression (53,54). Parental reactions to these difficult characteristics may moderate the ultimate impact of difficult temperament (55,56). From a diagnostic standpoint, longitudinal studies indicate that early ODD confers heightened risk for adolescent mood disorders (57,58). This outcome likely reflects the presence among ODD symptoms of several that highlight negative affect (anger, easily annoyed, etc.) (59,60).

Among youth with conduct problems, those with negative affect symptoms tend to be more aggressive and to experience worse functional outcomes. Unfavorable outcomes include more hospitalizations, police contacts, impaired social relations, substance abuse, and less improvement with treatment (61–65).

Emotion regulation can be disturbed episodically, with or without persistent problems in prevailing mood (26,66,67). Aspects of emotion regulation that are relevant to aggression include high emotional reactivity, poor emotion modulation, lability, and slow recovery from upset (68–71).

Aggressive behavior may also arise in the context of major depression and bipolar disorder. Heightened irritability and anger are frequent aspects of both disorders, so a lowered threshold for lashing out is not surprising, and the risk for self-directed harm among affected individuals is of course high. Among adults, comorbid substance abuse significantly raises risk of violent and suicidal behavior (72,73). Bipolar disorder may confer a higher lifetime risk for aggression than unipolar depression (74). Clinician-rated aggressive behavior may be less frequent among inpatient adolescents than adults with bipolar disorder (75), but there may be sample biases wherein adults are more likely to be hospitalized for dangerousness than youth.

Anxiety

With the reclassification or trauma-related disorders in DSM-5, the remaining anxiety disorders by themselves seldom increase the liability for aggressive behavior. The situation changes, though, when comorbid conditions enter the picture (76). Anxious children with ADHD and ODD are more likely to become behaviorally agitated, perhaps by virtue of impulse control problems making it more difficult for them to tolerate anxious discomfort. For instance, efforts to interrupt compulsive rituals for a child with obsessive–compulsive disorder or to enforce school attendance with a child who has separation anxiety can at times provoke reactive aggression.

Coldheartedness

Besides these "hot" affective features, callousness and *under*emotionality may, as mentioned earlier, influence aggressive behavior used for instrumental goals (77,78). These individuals appear to display rather blunted emotional reactivity to the distress of others, a stimulus that is thought to inhibit gratuitous violence in most people (79). Similarly, the disapproval of others appears to carry little significance for them and it seems they are more interested in asserting control and gaining advantage over others than in companionship.

Environmental Influences

Interpersonal Conflict, Trauma, and Stress

Diminished Positive Parental Interactions; Harsh and Inconsistent Discipline. Child-rearing practices probably affect the development of children's aggressive behavior though both stress-related and social learning processes, and the next section will focus on the latter. It is obvious that children with early-onset conduct problems often make difficult housemates, and those with frequent aggressive behavior still more so because family members are the most common targets (80–83). Even when the behavior is not particularly harmful, many aspects of family life that are normally almost effortless are fraught with the prospect that a meltdown or a "scene" will disrupt otherwise enjoyable activities, draw attention and resources away from siblings, and complicate relations with schools.

The compound effects are to corrode the quality of parent–child relationships, particularly when parents believe misbehavior to be volitional (84). Family stress and discord and frequent repercussions (85–88), which may further degrade a parent's capacity to apply measured discipline consistently and with composure (56,87,89–91). The mutual antagonism that results, and the child's own unpredictability, may incline a parent toward disengagement or involvement that

depends on the parent's own energy and mood, than on the child's behavior.

Parental psychopathology and substance abuse can also lead to suboptimal interactions with their children (92–94). Low maternal education and hostile/ineffective parenting behaviors both increase the likelihood that toddlers will show persistently high aggressive behavior at least through the start of middle school (95). However, this risk was reduced among preschoolers of low-education mothers who received nonmaternally provided day care (96).

Poor quality of a child's primary relationships, however it comes about, may predict a worse overall outcome and treatment prospects among those with behavioral volatility and aggression, after statistical adjustment for severity of behavioral problems and disciplinary practices (97,98). Interestingly, it has been suggested that among children with callous–unemotional traits, quality of parenting may play a *smaller* role in the development of their conduct problems (99), a finding that is consistent with the apparent indifference of psychopathic individuals to others' feelings.

Trauma, Abuse, Frequent Endangerment. Maltreatment and other direct trauma during childhood significantly increase one's liability for lifetime psychopathology. The largest effect size of child abuse for both genders is the increase in antisocial behavior (100). A connection between living helplessly with frequent, random infliction of pain and development of defensive hyperreactivity to even minimal threat is both intuitive and supported by recent studies indicating abnormalities in the structures and processes that subserve fear and affect regulation (101,102). Early maltreatment correlates equally well with measures of reactive and proactive aggression (103), and abuse was slightly more prevalent among youth categorized as proactively aggressive than reactively aggressive (104).

Peers and siblings can also inflict torment and fear that heighten threat sensitivity leading to self-regulatory problems and aggression. Bullying and other victimization experiences have recently gained overdue recognition as sources of distress that can culminate in harmful behavior toward others or oneself (105–107).

Community Factors. Studies focused on disadvantaged communities indicate that children's exposure to neighborhood violence is associated with both aggressive behavior and post-traumatic stress disorder (108). Exposure effects on development of aggressive behavior seem especially strong for highly stressed families with conflictual relationships (108).

Besides exposure-related risk, neighborhood socioeconomic disadvantage augments the risk for aggressive behavior in children, but the effect may be largest for children in single-parent households (109). It has also been suggested that the proportion of single-adult-led households may be a community-level risk factor (110). While single-parent homes are not inherently pathogenic, communities where they predominate have fewer adults providing supervision and those present are

more likely to be busy with the burdens of raising children with fewer resources than would be typical in child-rearing homes with at least two adults.

Social Learning

Benefits for One's Own Aggressive Behavior. If aggressive behavior has a payoff, basic learning theory would predict that it will be more likely in the future. Therefore, if a conflict involving the child's aggression ends with the child prevailing in getting his or her way, escaping from an undesirable situation, or gaining some other reward, aggressive behavior is in effect reinforced.

Likewise, victim acquiescence to one's aggressive behavior offers further incentive to attack or intimidate others. Some bullies may also attain high status among peers at least for brief periods (29). In addition, peer encouragement can also provide powerful inducement toward antisocial behavior that outweighs adult-imposed consequences for it. Vicarious enjoyment of a peer's antisocial conduct, and reinforcement for the performer, may be related to the findings that outpatient group treatments for youth with severe conduct problems may do more harm than good (111). A similar process may also occur by which a youth with severe conduct problems may enlist the collusion of sibling to erode the authority structure within the home (112).

Modeling, Observed Benefits for Aggression. The phenomenon of learning by observing the consequences that accompany behaviors modeled by *others* is called social or vicarious learning (113). The weight of the current evidence seems to indicate that high exposure to depictions of violence in mass media may contribute to the risk of aggressive behavior, particularly among young children (114). Similar effects have been shown for violent video games, but interestingly video games that involve cooperation have been linked to increased prosocial behavior.

Cognitive or Sensory Impairments

Several psychiatric and developmental disorders may have aggression as a complication because they distort one's information processing or the capacity to communicate and handle distress.

Aggressive behavior frequently accompanies schizophrenia among adolescents and adults (115,116). The few children who develop the disorder are more typically terrified, withdrawn and perplexed, rather than belligerent or agitated. Several factors that seem to augment the risk of violence include severity of positive symptoms, paranoid delusions, male gender, and premorbid history of aggressive behavior. Following stabilization of acute psychotic symptoms, violence does not seem especially characteristic of residual phase schizophrenia among adults, and indeed increased belligerence, suspiciousness, and lashing out often signify risk of

relapse, drug or alcohol use, or effects of other nonpsychotic disturbances (116).

Aggressive behavior is more prevalent in certain developmental major disorders than others. Aggressive behavior frequently occurs among those with autism spectrum disorders (ASD), and may be more severe than among those with other significant developmental disabilities (117,118). By contrast, it is less of a complication in Down or Williams syndrome (119). Within any given syndrome, as well as idiopathic intellectual disability in general, severity of aggression seems a function of lower IQ and male gender.

Self-injurious behavior is an aspect of several developmental syndromes. Difficulties communicating the nature and cause of discomfort, and a limited repertoire of behaviors to gain the attention of others, mandate careful assessment to identify the triggers for aggressive outbursts and consider environmental changes to reduce their impact.

Behavioral Pharmacotoxicity

Prescription Drugs: Complications of Therapeutic Use, Overdose

Medication regimens for many aggressive children currently involve coadministration of multiple agents (120–122). Pharmacotherapy may contribute to irritability and behavioral dyscontrol in idiosyncratic ways. Agitation or “activation” that accompanies selective serotonin reuptake inhibitor (SSRI) treatment seems more prevalent among children than adolescents (123). Stimulant medications may also worsen irritability among some youth (124), but this is often a dose-dependent effect. Compounds used mainly for nonpsychiatric reasons also warrant review when behavior changes. For instance higher doses of corticosteroids can precipitate aggressive behavior (125).

Drugs of Abuse

It is difficult to attribute any specific amount of aggressive behavior to the effects of alcohol and other substances, because the risk factors for substance use resemble many of those for aggression. Because chronic aggressive behavior in youth often originates before exposure to illicit drugs, we show substance abuse in Figure 5.1.3.1 as a sequela of conduct problems that in turn further impairs functioning. Adolescent-onset aggressive behavior, though, may coincide with drug and alcohol use. Drug use by adolescents, including cannabinoids, cocaine, and hallucinogens, may aggravate psychiatric illness among psychosis-prone individuals.

TREATMENT

Treatment Planning

Psychopathology and Context

This chapter emphasizes the significance of specific "underlying" psychopathology and other influences in the emergence of aggressive behavior, in large part because successful treatment of the primary disorder ameliorates aggression. An alternate view is that aggression, regardless of specific disorder, might be amenable to some antiaggressive treatment. Current practice and guidelines combine these approaches, especially in regard to pharmacotherapy (126–128). Generally, the primary psychiatric disorder should be the target of initial interventions. Then, if aggressive behavior does not subside adequately, other medications are often prescribed on the basis of their antiaggression effects. As a practical matter, the most common scenario, especially for preadolescents, involves initiating pharmacotherapy targeting ADHD symptoms among the large group of youngsters whose aggressive behavior develops in the context of ADHD plus a disruptive disorder or DMDD. Another large patient group shows aggressive volatility and agitation that accompany depression, usually among adolescents, which often raises concerns about bipolar disorder risk.

Clinicians therefore often face a decisional dilemma of how long and to what doses should one persist in trying to optimize first-line treatments (such as stimulants for ADHD) versus initiating an adjunctive medication (often antipsychotics that incur higher adverse effect risks) to achieve behavioral stability in troubling situations. There is only limited research to guide these choices.

Multiple Impairments in Several Settings Are Common

It is common for a child to exhibit aggressive behavior in one setting and other problems in other venues. For example, loss of control may be most prominent at home, but school problems can include academic frustration, low achievement, and social problems. Aggressive behavior at home may relate to these other stresses, and managing these triggers may be the key to reducing volatility at home.

Prioritizing and Sequencing Treatments

When psychosocial treatments should precede medications or vice versa, is a common issue. Family preference is a pivotal factor, and the pros and cons of each approach should be discussed openly along with an agreement about how to monitor the outcome and when to change course. Productive shared decision-making, however, requires well-informed partners. Many families would prefer to give nonpharmacologic treatments a chance, in which case it is worthwhile to find discuss their expectations for therapy. Most evidence-based psychosocial treatments for

youth conduct problems involve significant parental effort to change interaction patterns with the child, and to manage behavioral upsets in a firm but calm manner. When impulsivity and inattention are significant problems, behavioral therapies stand a greater chance of gaining traction when self-control and focus have improved somewhat, and medications for ADHD remain the most effective means to that outcome.

In any case, severe conduct problems that include aggression often have had a corrosive impact on family life, and relationships become fraught with negative expectations, resentment, or guilt. Whether or not formal psychosocial treatment is part of the plan, assuming it is even available, the child psychiatrist has to be mindful of these stresses and try to foster opportunities for family members to enjoy one another's company, and warmly recognize and support any progress toward handling troubling situations with greater composure.

Pharmacotherapy

A common view is that medication affects only reactive or impulsive aggression (129,130). However, trials involving impulsive youth indicate that proactive aggressive behavior often decreases alongside improvements in reactive aggression, and parent ratings of callous–unemotional features also decline (20,131–133). Nevertheless, among proactively aggressive individuals without contributing psychopathology (such as impulsivity, mood disturbances, etc.), pharmacotherapy currently lacks justification.

Stimulant and Nonstimulant Treatments When ADHD Is Present

Most controlled trials of stimulant medications for ADHD show treatment-related reductions in aggression and other conduct problems (35,131,134–137). However, very few of these trials involve patients selected for high aggressive behavior that is the primary outcome. Instead, ratings of conduct problems are most often secondary outcomes for patients with ADHD and no prespecified level of aggression. Some trials involve patients with a broad spectrum of disruptive behavior, not aggression per se (131,135,138).

More recent trials examining treatment strategies for children with significant aggressive behavior who have ADHD, though, indicate large effects following stimulant monotherapy on reducing aggression or a composite of disruptive behavior symptoms, as well as mood symptoms (20,26,133,139–141). These trials employed either extended or brief stimulant optimization, along with behavioral therapy, before starting adjunctive treatment risperidone, divalproex sodium (DVPX), or placebo. Across two trials using extended stimulant monotherapy optimization, 50% and 62% of children, all of whom had prior stimulant treatment before enrollment, showed

remission of aggression that obviated the need for adjunctive treatments. A trial using a briefer period of stimulant monotherapy before starting adjunctive risperidone or placebo, showed significant continued improvement for those randomized to placebo with no difference in overall responder rates, but an advantage on mean disruptive behavior ratings for those receiving adjunctive risperidone.

Two nonstimulant medications with affinity for noradrenergic α_2 receptors, the antihypertensive agents guanfacine and clonidine, have long been used to treat ADHD, and as add-on to stimulant targeting conduct problems including aggression. Long-acting preparations of these agents have made their use in this context more attractive, especially with their smaller adverse effect liability relative to antipsychotic treatment. They do seem to provide additional benefit to stimulant monotherapy for disruptive behavior symptoms when added to stimulants (142), but it is unclear from the relevant trials how often stimulant medication was optimized, nor was high aggressive behavior usually their focus. However, one small trial comparing methylphenidate and clonidine monotherapies with these drugs combined among aggressive youth with ADHD indicated that all three treatment approaches had comparable effects in reducing aggression (143).

Other approved nonstimulant treatments for childhood ADHD, bupropion and atomoxetine, have not yet been shown to affect aggressive behavior.

In the context of other primary disorders, the benefits of stimulant treatment on aggressive behavior are less well studied. Youngsters with major developmental disorders, autism in particular, have more variable responses to stimulant therapy, which at times may worsen aggression and irritability (144,145).

Antipsychotics and Antimanic/Mood Stabilizers

Antipsychotics. Antipsychotics have long held a prominent place in treating aggression in nonpsychotic individuals. Their broad spectrum of effects includes antimanic effects. Early studies suggested the efficacy of antipsychotic medications among nonpsychotic aggressive youth (146,147), but concerns about their potential to produce adverse extrapyramidal symptoms (EPS) and other unfavorable effects restrained their use. The advent of nonclozapine “second-generation” antipsychotic medications led to their wide use for nonpsychotic youth partly because they have overall lower risk for neuromotor adverse effects, at least among adults. Consequently, the past 15 years or so have witnessed a tremendous increase in the use of second-generation antipsychotics (SGAs) to treat severe behavioral disturbances in children (121,148–151). However, obesity, insulin resistance, type II diabetes, hypertension, and indices of atherosclerosis risk, known collectively as cardiometabolic adverse effects, are elevated among SGA-treated youth relative to non-SGA-treated youth (152,153). Children treated with these agents also remain more susceptible to EPS than adults with these agents (154,155).

Risperidone currently has the most extensive data from controlled trials supporting its efficacy as monotherapy among children with aggressive behavior (156,157). It has FDA approval for the treatment of irritability in autism. These studies show marked reductions relative to placebo in parent or clinician ratings of aggression and in some instances improvements in the asociality associated with autism spectrum disorders. Trials of risperidone added on to stimulant medication for aggressive children with ADHD (and without ASD or other developmental handicap) also show some advantage over placebo, but of smaller magnitude than risperidone monotherapy trials (133,158). Weight gain and hyperprolactinemia are frequently reported.

Aripiprazole also has an indication for irritability and aggression for 6 to 17 year olds with autistic disorder. Despite widespread clinical use for aggression outside of psychosis or autism, controlled trials for other populations are pending.

Two other SGAs marketed in the United States have adverse effect profiles that make them generally inappropriate for youth without psychotic illness: olanzapine's weight gain risk is very high, and ziprasidone has the highest risk for QTc prolongation (159). Lurasidone seems to have lower weight gain liability among adults relative to SGAs currently prescribed to youth, but was no more effective than placebo for irritability in autism (160) and EPS risk is higher than other SGAs (159).

Mood Stabilizer Agents. The use of lithium and anticonvulsant medications that have indications for mania (often referred to collectively as "mood stabilizers") for aggressive behavior among youth has been largely overtaken by SGAs. For some patient groups, however, the adverse effect profile of these treatments may be more favorable than SGAs.

Supportive data for lithium came from a few inpatient studies, and there are to date no outpatient trials that have shown its efficacy (130,146,161). A recent outpatient trial involving children and adolescents with bipolar I disorder showed improvement on symptom severity ratings compared with placebo, which may spur renewed interest on potential antiaggressive benefit for a subgroup of patients with primary mood disturbances (162).

A trial of adjunctive DVPX for children with ADHD whose aggressive behavior was refractory to optimized stimulant monotherapy showed higher rates of remission than those who received adjunctive placebo (140). A study using a similar stepped treatment approach but stimulant-refractory randomizing patients to adjunctive DVPX, risperidone, or placebo also showed advantages for DVPX over placebo on aggression and other measures of conduct disturbance. However, the magnitude of improvement for children who had stimulant plus either DVPX or risperidone cotherapy was substantially less than for the 64% of children whose aggression remitted after the stimulant monotherapy protocol.

Trials of DVPX monotherapy in more patients with more heterogeneous conduct

or mood problems also showed greater improvement relative to placebo (163–165). For youth with bipolar disorder, reductions in aggressive behavior accompanied DVPX treatment and were comparable to quetiapine (166), though among 10 to 17 year olds with bipolar I disorder extended-release DVPX was not more advantageous than placebo (167).

Carbamazepine treatment was associated with reduced aggression among hospitalized preadolescents with conduct disorder (168), however a randomized controlled trial at the same facility showed no benefit over placebo (169).

Antidepressants, Anxiolytics, Micronutrients

Despite the general principle that encourages choosing initial pharmacotherapy for aggressive or volatile patients based on his or her primary psychiatric disorder, there are practically no data on this approach for young people with major depression. Reluctance to include rage-prone adolescents in clinical trials is understandable, because the risk for harms is greater than among those who are less behaviorally activated or experiencing psychomotor retardation. Concern that such a symptom picture portends conversion to bipolar disorder also often dissuades clinicians from antidepressant monotherapy, even though data are lacking on the true magnitude of such risk compared to the risk of "overtreatment" with antipsychotic medications.

In clinical practice, adjunctive treatment with SSRIs for irritable youth with comorbid ADHD is not uncommon, but there are no data to support or denigrate this strategy. Trials of stimulant and adjunctive SSRI treatment for youth with DMDD are in progress.

Benzodiazepines may increase disinhibition and aggression (170) and are disfavored for treating childhood aggression outside acute management for agitation associated with psychosis.

One intriguing double-blind controlled trial conducted in a British penitentiary showed marked reductions in violent incidents among inmates randomized to receive a combination of vitamins, and omega-3 fatty acid pills compared to those who received matching placebo pills (171). The fact that this study effectively standardized all other aspects of environment and diet appears to strengthen the potential significance of micronutrients in violence-prone populations.

A recent trial with 11 and 12 year olds evaluated micronutrients, including three common omega-3 fatty acids, crossed with cognitive behavioral treatment (CBT) emphasizing anger control and reappraisal strategies (172). Child self-reports of reactive aggression showed larger reductions among those who had CBT plus nutrient supplementation than CBT and control groups. However, parent reports of externalizing behaviors showed no treatment effect.

Psychosocial Treatments

Overview

Interventions to reduce aggressive behavior alter the environmental context that promotes it, help individuals develop alternatives to aggression that meet their goals more adaptively. Other chapters contain descriptions of specific therapies for these purposes (consequence-based approaches, anger control, multisystemic therapy, etc.). This section offers a framework to appreciate at a more general level the avenues through which treatments may reduce aggressive behavior. Borrowing from the framework of functional behavior assessment we organize the discussion to show how psychosocial interventions try to make aggressive behavior *irrelevant, ineffective,* or *inefficient* (Figure 5.1.3.2) (173).

Make Aggression...	*By...*	*For instance*
Irrelevant	**Changing antecedents**	* Modify demands and way of communicating them. * Avoid problem situations. * Provide attention before negative attention-seeking behavior. * Reduce provocation and frustration. * Restrict access to peers who promote misconduct.
Ineffective	**Changing consequences**	* Behavior does not reap positive outcomes. * Incentivize alternatives. * Behavior does not visibly "rile" adults. * Negative consequences for problem behavior.
Inefficient	**Developing alternatives that fulfill the same need as aggressive behavior**	* Skills training (social, anger management). * Improved communication of needs. * Involvement in positive activities that emphasize strengths. * Alternatives such as chill out time.

FIGURE 5.1.3.2. Goals and approaches of psychosocial treatment.

Make Aggression Irrelevant

Aggressive behavior is generally not a random event. Situations, or antecedents, usually trigger problem behaviors, these antecedents affect patients to differing degrees. One approach is to reduce exposure to these precipitants. From a functional viewpoint, if aggression is the child's "solution" to that situation, minimizing exposure to that situation makes aggression irrelevant. If a child frequently fights with a sibling when they're both in their shared bedroom together in the morning, then it seems sensible to have child eat breakfast while the other is getting dressed, then switch. A reminder to get homework finished might precipitate arguments, escalation, and finally an explosion. Enrolling the youngster in an after-school program that includes homework may help. The same idea also applies to reducing exposure to situations that actively encourage problematic behavior. Curtailing a youth's exposure to behaviorally deviant peers is one example (174).

Besides avoiding situations that provoke aggressive responses, increasing exposure to situations that already lead to cooperative behavior is another way in

which altering antecedents can make aggression irrelevant. After reaching high rates of cooperation and exposure by asking the child to do only things he or she would want to do anyway, one then moves on to requests that the child had hesitated to do before (175).

Make Aggression Ineffective

How other people react to aggressive behavior might maintain or reinforce it. If outbursts lead others to acquiesce, or, alternatively, remove the child from a situation he or she wanted to escape, then problem behaviors are essentially rewarded. Changing consequences of aggressive behavior would therefore make it ineffective in achieving the goal that sustains it. Contingency management approaches (reward systems, time out, and the like), or ignoring milder misbehavior altogether, makes aggressive behavior less effective by diminishing the “payoff” that previously reinforced it.

Similarly, bullying and intimidation become ineffective if the social milieu expresses intolerance for the behavior, rather than fear and subservience. This often means supporting victims who come forward as the real “heroes” so that a community undermines the secrecy and fear on which such behavior thrives.

Make Aggression Inefficient

If the purpose that aggressive behavior seemed to serve can be achieved with behavior that is easier to perform, then aggression becomes relatively inefficient, and should reduce in favor of the alternative. Many skills training interventions (anger management, social skills training, problem-solving, etc.) develop proficiency in alternatives that enable a child to cope with otherwise aggression-provoking situations more adaptively. However, one has to take care that these alternatives really are easier for a given child, and make sure that the alternative has the desired result. One can teach a child to ask to borrow something, but if limited verbal skills make it harder rather than easier relative to grabbing, altercation can follow. Likewise, if the other child does not willingly share then “asking behavior” may not be reinforced. “Bridging” can help smooth the process, where the child can easily signal to an adult that he or she wants something from another child and the adult facilitates the exchange, and reward the child for handling a rebuff with composure. At the other end of the age range, if an adolescent had obtained some social esteem by being antisocial, consider exploiting his or her prosocial talents and interests as a vehicle to gaining prestige.

Selected Trials of Psychosocial Interventions for Aggressive Behavior

A range of psychosocial interventions exists for children and adolescents with

various conduct and oppositional defiant behaviors, often including aggression. Treatment studies targeting aggression per se have been somewhat less common. Nonetheless, various psychosocial treatment strategies have yielded significant reductions in aggressive behaviors, both in prevention trials and clinical treatment settings (176–180). Thus, parent management training (PMT) is an efficacious strategy for treating aggression and related conduct problems (176,179,181,182). Some evidence suggest that PMT may yield durable improvements in behavioral problems across various settings (183). Parent–child interaction training (PCIT) has also been found to reduce aggressive symptoms among young children, in large part through making parental attention and positive engagement a scheduled an enjoyable time to reduce child reliance on negative behavior for attention (184). Individual and some group-based cognitive-behavioral treatments, including anger management training and problem-solving skills training, have also had some success in improving aggressive behavior (177,178,181,185–187).

CONCLUSIONS

Nevertheless, aggressive behavior still eludes consistently effective intervention. The combined force of troubling outcomes, adverse community impact, high prevalence, and uncertain treatment prospects propels childhood-onset aggression to the forefront of challenges in mental health today. Timely and thoughtful assessment and intervention may save a child from a spiral of chronic conflict, social maladjustment, and marginalization. The child psychiatrist has an especially privileged position because the complications that arise from chronic antisocial behavior cause their own hardships, lifestyle problems, and impairments that make successful treatment far less likely.

CHAPTER 5.1.4 ■ FIRE BEHAVIOR IN CHILDREN AND ADOLESCENTS

STEVEN J. BARRETO, JOHN R. BOEKAMP, ELIZABETH L. REICHERT, KAREN R. HEBERT, AND MARGARET PACCIONE-DYSZLEWSKI

INTRODUCTION

All children will naturally be exposed to fire during the early years of life. It is part of the normal course of development that they acquire knowledge that is linked both to mastery over fire and its potential for destruction and harm. In contrast to the development of fire interest, the emergence of fire behavior in children and adolescents carries with it the potential for death, injury, and property loss of striking proportions. Children who become involved with fire early in life, and those who use fire in an unsafe and destructive manner, are at risk, not only for continued involvement with fire, but for psychopathology and behavioral problems. The challenge for clinicians is meeting the need for early identification of children at risk, in order to help parents and caregivers curb maladaptive forms of fire activity that may lead a child down a maladaptive developmental pathway.

Individual Factors

Age; Gender; Learning/Problem Solving Skills; Emotional and Social Problem Solving; **Motivation**; Perception of Danger and Safety Skills; Executive Functioning; Social Competence; Psychological Functioning

Parenting Factors

Monitoring, Providing Attention; Tracking Child Behaviors, Structuring Time, Supervision; Access to Incendiaries; Teaching and Modeling of Fire Safety Skills; Communication; Behavior Management; Relationship Quality

School, Peers, Neighborhood & Culture

Support System (e.g., role models, friends, after school programs); Neighborhood Responsiveness and Prevention Education; Poverty; Government (e.g., policies and legislation)

Fire Involvement

FIGURE 5.1.4.1. The ecologic–transactional model of juvenile firesetting.

In this chapter, we summarize the literature on juvenile fire behavior, presenting a foundation for assessment and intervention. In this review, we will define the phrase juvenile fire behavior as including both intentional firesetting and unintentional and unsupervised match and lighter play. The term juvenile fire-setting will be used to refer to intentional fire-starting. The term fire involvement will be used to refer to the widest range of fire behaviors including pulling of smoke/fire alarms, hiding matches/lighters, or bomb-making. Occasionally, we will identify where the term fire involvement is defined in a more restrictive manner by an instrument or specific study. In child psychiatric settings, the behavioral health clinician occupies a critical role in adequately identifying children at risk, and offering treatment options that

decrease the likelihood of maladaptive developmental outcomes. We will present an ecologic–transactional model (Fig. 5.1.4.1) of the development of fire behavior that can serve as a foundation for research, but also a heuristic for clinical practice. We view this model as more accurately capturing the complexity of the developmental nature of fire behavior when compared with dominant motivational typology models. The ecologic model will suggest characteristics of both maladaptive and adaptive pathways of fire behavior. Throughout the chapter, we will stress that fire behavior carries both short- and long-term risks, ranging from more immediate concerns including property damage, risk for human injury, behavioral problems, and psychopathology to more destructive forms of fire play potentially emerging at a later point in development. We will review important considerations in the clinical evaluation of fire behavior and follow with a contemporary selection of the empirically supported educational and psychosocial interventions.

PREVALENCE, RISK, AND DANGER

Youth who engage in unsupervised fire behavior pose a significant threat to the health and safety of every community throughout the United States. Annually, fire behavior among children accounts for thousands of uncontrolled fires, millions of dollars in property damage, as well as injury and death (1–5). The number of incidents of injury and death is cause for concern. From 2004 to 2008, there were 57,700 fires attributed to youth associated with over 100 civilian deaths and over 900 civilian injuries and $286 million in direct losses (6). Arson is the charge most likely to bring a child under 10 in contact with the legal system, as children aged 10 and under are arrested for arson more than for any other crime (7). Of the individuals arrested for arson in 2009 in the United States, 45% were under the age of 18 (8).

Although prevalence rates vary considerably, it is clear that juvenile firesetting remains an issue of significant clinical concern. Among child and adolescent psychiatric samples, incidence of firesetting has ranged from 2.3% to 15% for outpatients, and 14.3% to 34.7% for inpatients (2,3). Statistics from community samples have been somewhat more variable, with estimates ranging from as low as 3% (4), as high as 45% (5), and with over 80% of males noted to be interested in fire and fire play. As these data suggest, firesetting is a problem affecting boys more frequently than girls (6). In a review of 22 descriptive studies, Kolko (9) found that 82% of identified firesetters were male and the age of these children was on average 10 years, with older children having more extensive firesetting histories. Although prevalence estimates have focused primarily on US samples, juvenile firesetting is a problem in other countries as well (10).

Two recent community sample studies found nearly a third of adolescents reported engaging in firesetting within the past year (11,12). According to the data collected from the Melbourne (Australia) Metropolitan Fire Brigade, nearly 20% of all

reported fires are started by children (2). Further complicating the problem are the high recidivism rates among youth, with up to 59% engaging in recidivistic behavior (4,13,14).

These statistics are alarming and underscore the seriousness of juvenile firesetting. Among children, fires started by children annually number in the thousands, leading to millions of dollars in property damage, severe injury, and even death (1–5). In fact, fires and burns have been documented as the fourth most common cause of unintentional injury-related death, resulting in more than 4,000 deaths each year (1,15). In 1997, statistics documented that 8% of deaths from residential fires occurred as a result of children's fire behavior, most often the result of the unsupervised use of lighters and matches. Furthermore, a survey conducted by the National Association of Fire Marshals determined that children were responsible for nearly 100,000 fires annually causing more than $250 million in property damage (5). This research clearly highlights the substantial role that children play in fire-related damages, injuries, and deaths. The damages resulting from fires set by children are likely much larger than these estimates suggest; as many fires set by children are never reported to fire departments. One study indicates that as few as 10% of all fires set by children are ever reported to the appropriate authorities (2,16).

ETIOLOGY AND DEVELOPMENTAL PATHWAYS

Although most descriptive studies have focused on dangers immediate to juvenile fire behavior (e.g., property loss, injury, death), enduring developmental outcomes associated with early fire experimentation are of integral importance to correction and prevention efforts. Interest in and attraction to fire is a common feature of childhood (14,17–22). Early fire curiosity and activity that are ignored or dismissed by supervising adults can lead a child down several possible maladaptive pathways. In a study of males aged 5 through 9 years, researchers found that interest in fire was almost universal across the sample, with one-half of the boys actually engaging in fire behavior, often in the form of match or lighter play (23). Some children become involved in early fire activity that leads to continued experimentation and heightened interest and fascination in later childhood and adolescence. Other children remain interested in fire but cease to engage in fire behavior. Still others remain interested and engage in planned and deliberate fire behavior with the intention of causing damage or harm. The present section will serve to explore the etiology and developmental pathways associated with early fire play and eventual firesetting behavior. Recognizing risk may be the first step for parents and supervising adults in altering maladaptive developmental outcomes.

We present an ecologic–transactional model that integrates theory and empirical findings (Fig. 5.1.4.1). This model describes the individual, family, social, and

ecologic factors associated with the onset and perpetuation of juvenile fire activity. Elements of these factors may combine to place a child on one of several pathways associated with dangerous fire behavior. As children mature, their cognitive and emotional development may place them at risk, or protect them against, engagement in destructive or dangerous fire behavior. Broadly, risk factors include the child's individual characteristics and motivational repertoire, parental and family features, as well as peer group factors, and school and community characteristics (24). It is important for clinicians to identify early distinguishing characteristics of juvenile firesetters so that intervention efforts can build upon strengths, target problem behaviors, and broaden the child and family's problem-solving repertoire, to protect against deviant developmental pathways and long-term maladaptive outcomes (25,26). In the present discussion, a focus will be placed on elements of the model that may contribute to the development of fire competency in children, despite exposure to conditions of adversity or the experience of failures at early points in development.

As the ecologic–transactional model highlights, individual risk factors include age, gender, cognitive ability, fire safety knowledge, social competence, executive functioning, as well as overt and covert delinquent behavior (27–29). Males, particularly those in the elementary and middle school years, are at high risk for fire experimentation. Furthermore, even younger children (ages 3 to 8) are at risk for fire behavior that may be associated with higher base rates of inattention and impulsive behavior, as well as a limited understanding of the consequences of fire behavior (30). Others have found juvenile fire behavior samples to be socially immature, isolated, and overall socially incompetent (9). Children who have firesetting histories have also exhibited a higher incidence of other emotional and behavioral disturbances (18,31). In one pathway, limited social competence and diminished learning capacities can be associated with noncompliance, impulsivity, hyperactivity, emotional dysregulation, and reactive–aggressive behavior, creating a constellation of elements placing the child at risk of firesetting behavior. In another pathway, individual factors may combine to place a child at risk of overt and covert conduct problems and delinquent behavior including the destruction of property, stealing, lying, running away, and truancy. The presence of these behaviors may increase the child's risk for engaging in firesetting behavior (9). In a study of 3,965 adolescents of grades 7 to 12, 27% reported firesetting in the last year, with over 13% reporting 3 or more episodes. Teens who persisted in fire behavior were more likely to report psychiatric distress, binge drinking, cannabis use, and sensation-seeking behaviors. This study highlights the association of psychopathology and substance use among adolescent firesetters (12). More generally, externalizing problems are thought to be developmental antecedents to fire behavior by some researchers (27), with others suggesting that firesetting behavior is an extreme form of conduct disorder (32).

In addition to the learning capacities and the frequency and intensity of disruptive

behaviors, the child's emotion regulation skills play a significant role in early fire behavior. This construct has been subsumed under the domain of motivation (33); however, we think it is important to examine self-regulation skills separately to clarify a child's capacity for self-soothing, self-control, responsiveness to emotional stimuli, and the capacity for self-monitoring emotional status. We have suggested elsewhere that curiosity and anger may be emotional triggers for firesetting behavior (16). Curiosity has demonstrated strong associations to parent reports of internalizing and externalizing behavior problems in clinical samples of children who have engaged in fire behavior. Some children who display excessive curiosity may be more emotionally dysregulated and display more frequent, earlier, or more significant forms of fire involvement (34). Compared to firesetting children scoring high on curiosity or interest, children reporting elevated anger have lower levels of psychopathology by parent report, and may engage in more deliberate and destructive involvement with fire (34). These findings highlight the possibility that difficulties regulating intense emotion (e.g., curiosity, fascination, or anger) influence the child's development of maladaptive strategies or skills that lead to potentially more destructive forms of fire play. It will be fruitful for future studies to examine more closely the effects of emotional dysregulation and its relationship to juvenile firesetting.

The child's individual characteristics need to be considered in his/her environmental context to clarify risk of firesetting when evaluating developmental pathways toward firesetting. Cognitive behavioral models emphasize how children's behavioral repertoires develop through observation, modeling, and conditioning processes. Researchers have noted that early fire experiences, access to incendiary materials, family members who smoke, and siblings and peers who have had a history of firesetting all contribute to the child's development of maladaptive strategies which may increase the risk of firesetting (16,18,19,24). In an early study, juvenile firesetting was found to be more frequent among boys whose fathers' occupations directly or indirectly involved the use of fire when compared with those children whose fathers' occupations were unrelated to fire (35). Furthermore, child and adolescent firesetters have reported more frequent observation of friends and family members who smoke and use fire regularly (28). Kolko and Kazdin (24) report that access to firesetting materials alone can provide the conditions sufficient for children to become involved in fire-related activities (a child who uses a candle to light paper on a stove). Accessibility may be facilitated by peers or adults who model smoking or other fire-related behaviors or who carelessly leave materials accessible to children. Observation and modeling appear to be an important mechanism in the development of fire behavior.

Fire-related learning, impulse control, and emotional dysregulation are influenced by the family context. Familial risk factors for trajectories leading toward firesetting behaviors include parental psychopathology, emotional distance and communication,

harsh disciplinary strategies, limited supervision, and stressful life events (28,34,36). For example, parents of juvenile firesetters have been found to demonstrate a significantly greater incidence of psychological disturbance including schizophrenia, other psychotic disorders, depression, and substance abuse. Parents of juvenile firesetters have also been found to be less nurturing, unresponsive, and at times rejecting (27,34). These relationships have been described as conflict laden and unaffectionate (34) and frequently involve limited communication between parent and child. A prospective study found a link between marital violence, paternal abuse of animals, paternal alcohol use, and children's firesetting behavior (37). Additional work has documented a significant relationship between parental disciplinary strategies and fire behavior. In particular, research suggests that juvenile firesetters tend to come from families who either use unduly harsh punishment practices (38), or mild, less-effective, forms of discipline (28). Related to this finding, researchers report that prolonged absence and insufficient supervision from parental figures can also lead to engagement in antisocial behavior (34). Left to their own, children are more likely to participate in covert behaviors and may even act out in an effort to engage otherwise inattentive parents. Moreover, stressful events such as a death in the family, divorce, or the introduction of a new step-parent may also be associated with firesetting among children and adolescents (27). Taken together, these findings suggest that ineffective parenting patterns are both directly and indirectly linked to firesetting.

As the ecologic–transactional model suggests, children's developmental pathways are also linked to other social and ecologic factors including peers, school, neighborhood, and culture. The presence or absence of a support system, the community's response to fire behavior, and government policies and regulations are all factors that can contribute to a child's risk of continued fire involvement. For example, exposure to peers who smoke or engage in fire activity themselves may contribute to a child's risk for early fire experimentation. Moreover, peer support and attention can serve as significant reinforcers for juvenile firesetters (39), particularly because these children tend to grapple with social skill deficits and often are not accepted by the peer group. However influential the peer group, community response to a child's early fire behavior can have significant impact on continued involvement with fire as well. For example, educational intervention and awareness programs provided by fire departments and other community organizations may be effective in reducing the frequency and severity of children's firesetting behavior (2,15). Over the past several years, major insurance companies have sponsored training opportunities for parents and providers working with juvenile firesetters and associated intervention coalitions (40). The juvenile justice system plays a role in the diversion of youth who are charged with arson (41) and, in many cases, coordinates or provides behavioral health treatment (42). Delinquent youth may be at risk of firesetting but charged with other crimes. The continued allocation of public and

private resources in support of interagency collaborations and networks that support fire-specific intervention efforts is crucial.

The influence of cultural values regarding fire use and the level of assimilation of families is an unexplored, but potentially significant, factor in firesetting behavior. Less industrialized societies expose children more regularly to fire use for instrumental purposes (cooking, heating, agriculture/crop maintenance). In one case anecdote, a child referred for fire-starting, whose family had recently immigrated from the Dominican Republic, was receiving inconsistent messages regarding fire safety from his mother and grandfather. While his mother emphasized the importance of never using fire without proper supervision and responded with firm prohibition and consequences for this behavior, his grandfather disregarded this approach to home fire safety, noting that in their country of origin, he would be encouraged to use fire without supervision at an early age to meet developmental expectations.

PSYCHOPATHOLOGY AND FIRE BEHAVIOR

As our discussion of risk factors implies, the pathways to juvenile firesetting are multiple and interactive. For example, there is no clear evidence that early fire experimentation and activity causes later fire behavior. Some of the complex factors that influence an early fire-starter's later fire behavior include (1) the individual child's developmental maturation, together with impulse control and behavioral inhibition, emotion regulation skills particularly pertaining to fire fascination/curiosity, anger, and loneliness, and the development of social competence; (2) parenting practices including warmth, attention, monitoring, behavior control and discipline, communication, and modeling of safe behavior in the presence of fire; (3) the influence of peer modeling expectations; and (4) the constructive response of the neighborhood as well as the availability of ongoing prevention and intervention collaborative efforts in the community through fire service, juvenile justice, and behavioral health networks. Studies of juvenile firesetting have focused on the association of psychopathology to early fire experimentation and activity that are related to individual risk factors. Although over the years an emphasis has been placed on externalizing symptoms, likely because these features are more observable and intrusive to adults, research has also shown internalizing problems to be significantly related to early fire activity.

Externalizing problems including aggression and covert behavior such as lying and stealing are the most frequently cited correlates of early firesetting (17,29,33). A great deal of empirical work has associated firesetting diagnostically with conduct disorder (32,36,43–45) and firesetting is one of the symptoms of conduct disorder in the DSM-5. For example, when compared to a group of children who had committed murder, firesetters aged 10 through 17 were found to have higher rates of previous violent offenses, and they also were more likely than the homicidal group to carry a

diagnosis of conduct disorder (43). Among clinical populations, several authors have noted that the primary reason for referral among firesetters was not for fire activity per se, but rather other externalizing symptomology (e.g., hyperactivity, truancy, running away, destructiveness, aggression) (24,27). As noted previously, some theorists suggest a developmental framework for understanding firesetting amid other kinds of disruptive behavior. Specifically, early fire activity is conceptualized as part of a deviant pathway characterized by stealing, lying, and other kinds of antisocial behaviors, only eventually ending in fire activity or arson (27). Alternatively, some have suggested that fire behavior signifies an extreme form of conduct disorder (32). A recent prospective study of six 12-year-old children found that reports of firesetting increased the likelihood of delinquent behavior within the following 10 years by as much as 2- to 10-fold (37).

We do not view firesetting as isomorphic with antisocial behavior, as there is clearly a much larger and heterogeneous group of children at risk of firesetting. For example, in several comparative studies of firesetting, delinquency, and other kinds of violent offenders, juvenile firesetters with and without histories of delinquent behavior did not differ across multiple domains (36,46,47). These authors determined that firesetters tended to demonstrate the same kinds of behavioral problems as children who had no previous history of fire experimentation, but who were classified as delinquent for other reasons. However, recent research has suggested that even when a fire safety education (FSE) intervention is administered, juvenile firesetting behavior may be a marker for significantly increased risk of future antisocial or criminal behavior in an important and large subgroup of youth (48).

Although externalizing behaviors tend to be the most widely cited and observed correlates of early fire activity, internalizing problems should not be overlooked. Researchers have found some significant associations between fire behavior and the presence of depressive and anxious characteristics. For example, in an investigation of the personality profiles of adolescent firesetters, investigators found that these teens scored significantly higher than non-firesetters on scales of depression, alienation, and on symptoms such as fear, worry, and withdrawal (49). In the prospective study mentioned earlier, firesetting and cruelty to animals were shown to be related to depression as well as conduct disorder, ADHD, and ODD (37). Furthermore, it has been noted that juvenile arsonists tend to have heightened suicidal thinking and an increased risk of suicide attempts (50). These children frequently have been involved in recent stressful life events including separations, divorces, and deaths in the family (17,27), all of which tend to heighten internalizing symptomology such as anxiety and depression. In an investigation of female firesetters, depression and low self-esteem were cited as significant antecedents to fire activity (51). Nevertheless, depression and anxiety are reviewed much less often in the firesetting literature than aggression and conduct behaviors. Studies that rely on

parent report may be more likely to document associations between externalizing symptom and juvenile firesetting because externalizing behaviors are more easily observed, compared to internalizing symptoms which are more reliably endorsed through child self-report. As such, while the majority of research suggests firesetting is mostly associated with disruptive behaviors, anxious and depressive symptomology should remain a clinical consideration. Of particular interest are children with a mixed constellation of externalizing and internalizing psychopathology. These are children who may have multiple diagnoses over their lifetime (e.g., ADHD, ODD, mood or anxiety disorder) who are at risk for a variety of behavioral problems (e.g., impulsivity, irritability, emotion dysregulation, defiance, noncompliance, self-injury, or reactive aggression toward others). Such children may not be as likely to endorse anger as a primary motivation for firesetting and they may struggle with family environments lacking in critical parenting practices of monitoring, structured and responsive behavior management, warmth, and attention.

Two additional clinical considerations are social skill deficits, briefly reviewed in our discussion of etiology and developmental pathways, and substance abuse. Both are strongly associated with psychopathology as well as firesetting among children and adolescents. Kolko, Kazdin, and Meyer (29) conducted a comparative study of firesetters and non-firesetters, and found that firesetters demonstrated significantly lower social ability than their counterparts. In a follow-up work, this same finding has been consistently reported (24,33,51). Some have suggested that firesetters are averse to social interaction, and therefore are less likely to develop solutions to problems via socially acceptable routes (33). This aversion may lead to acting out aggressively, and indirectly, in the form of fire play, when a child's limited problem-solving repertoire leads to the aversion of assertive social confrontation and the expression of aggression through covert fire behavior. Another maladaptive pathway is through fire experimentation as a method by which to gain the attention and, potentially, admiration of peers, by children who are unable to do so by more skillful methods.

In addition to social skill deficits, substance abuse has also been implicated in the constellation of psychiatric difficulties observed among adolescent firesetters. Specifically, this population is noted to have difficulties including alcohol dependence (52) and inhalant abuse (50). We view substance abuse as likely linked to increased impulsivity through disinhibition contributing to poor decision making in critical areas of fire competence (e.g., fire safety knowledge and reasoning). The combination of social skill deficits and substance abuse may be associated with deviant peer socialization that may place a child at greater risk of engaging in firesetting behavior and other serious rule-violating behaviors.

FIRESETTING TYPOLOGIES AND CATEGORIZATIONS

Over the last half century, clinical theorists have attempted to identify a typology of firesetters in which different motivations (such as curiosity or anger) are thought to influence recidivism or severity of fire behavior (33). It has been suggested that children's motivation for becoming involved in fire play is predictive of continued involvement with fire as well as other forms of antisocial behavior (33). Several taxonomies have been suggested (39,53–55). For purposes of integrating these categories and typologies into the ecologic–transactional model, we organize these into four domains: fire curiosity/excitement, family dysfunction and parenting practices, and delinquency and conduct disorder, and serious psychopathology (such as psychosis or the diagnosis of pyromania).

Fire Curiosity/Excitement

By far, the most well-known category is that of the child who is motivated by curiosity (17,50). Retrospective studies of incidents reported to fire departments over the span of several years have demonstrated that a clear majority of fires and fire play were the result of curiosity (56,57). In retrospective incident report studies, the term curious refers to a child who has few to no behavioral difficulties and is in the early stages of fire experimentation (54). These studies, and the broader definition of curiosity, continue to influence strongly the firefighter literature that has driven much of the continuing education and training, particularly among fire education specialists. This literature describes children in the curious category as unlikely to set fires again after receiving FSE, with less-intensive intervention assumed to be warranted. In the past, research reported the curious firesetter to be less pathologic, younger, and generally only involved in one serious fire incident across the life span (17).

The curious firesetter categorization, however, is evolving and has been expanded by more recent empirical findings. Specifically, Kolko and Kazdin (33) found that children motivated to set fires by curiosity were also found to demonstrate elevations on measures of psychopathology including internalizing and externalizing dysfunction, overt and covert antisocial behaviors, expressed hostility and social skill deficits. These children also had more early experiences with fire and reported to be more interested in, exposed to, and in contact with fire over the previous year. This was in contrast to children scoring high on anger, who did not show more psychopathology than those low in anger, but had greater exposure to models of fire interest, elicited more community complaints about fire behavior, and were more frequently hiding matches or incendiary materials. These findings suggest that curiosity, when compared with anger among firesetters, is more strongly associated with a different constellation of risk factors that combine into distinct maladaptive pathways. The findings also suggest that the broader type of curiosity, associated

with one-time fire experimentation, and thought to be developmentally common in children, may be distinct from fire curiosity/ excitement as identified in studies using the Firesetting Risk Interview (FRI) or the Children's Firesetting Inventory (CFI) (18,19). The comparatively smaller group of children described by these measures may show more psychopathology, hostility, social skill deficits, and engage in more disruptive behaviors than those children in the more broadly curious category. High levels of curiosity, as measured by the FRI/CFI, may be associated with heightened risk for repeat fire play and/or intentional firesetting behavior. Fire interest/excitement and antisocial behavior have also been linked to more severe and persistent firesetting (14,22). Similar to some children with high levels of anger, some children with high levels of fire curiosity and excitement may set fires with a specific intention to harm (33).

Family Dysfunction and Parenting Practices

Children may also set fires as an individual expression of family dysfunction or a response to overwhelming life or family stress. This stress may be related to deficits in family functioning such as parental modeling around fire, communication, monitoring, behavior control, or parental psychiatric illness. In this category, children are thought to be inadvertently using fire as way of calling out for help (17). Several researchers have indeed found firesetting to be intimately tied to family and life stressors (17,27,36). We term this second category family dysfunction and parenting practices. This family dysfunction and parenting practice group includes families where there is an association between child maltreatment and juvenile firesetting. In a review of 4,155 youth in the child welfare system, results suggested that children were three times more likely to engage in firesetting behavior (58). A study of 205 juvenile firesetting youth (ages 4 to 17) showed 48% to have a history of maltreatment. Among this group, firesetters had an increased likelihood of family stress as a motivating factor, used more versatile ignition sources and targets, and showed higher rates of recidivism (59).

Delinquency/Conduct Disorder

The third category refers to children who become involved with fire as part of the development of a pervasive pattern of antisocial behavior. This category (17) may represent a distinctive maladaptive pathway (32). This category may also include many children scoring high in anger and thought to be engaging in firesetting that is more purposive or deliberate than children in the family functioning and parenting practices category. However, this relationship has yet to be tested. This group may also include those youth who are at risk for reoffending through delinquent behaviors other than firesetting, even after firesetting educational intervention has been

received. A 10-year follow-up study of offending behaviors among 182 child and adolescent firesetters in New Zealand showed that while arson recidivism was only 2% for this sample, rates of other offending behavior were high with 59% of the sample reoffending during the follow-up period (12.8% imprisoned, 40% rated as moderate, and 4% rated as minor offenses). Offending behavior was predicted by the experience of abuse. Involvement in family violence was associated with more severe offending behavior. Living in a two-parent home was associated with decreased likelihood of offending behavior. Results suggested that repeat firesetting (in this study, defined by more than one incident and representing more than the half of the sample) significantly predicted the risk of later offending behavior (48).

It has been speculated that enuresis, cruelty to animals, and firesetting are not only highly correlated to one another, but also predictive of violent crimes later in adulthood (17,27). Two studies have failed to identify a relationship between firesetting and enuresis (47,60). However, juveniles reported to be cruel to animals have been shown to be more likely to engage in repeat firesetting when compared with children not cruel to animals (60). It is possible that the behavior of cruelty to animals when combined with firesetting will increase the likelihood of subsequent delinquent behaviors (37), thus signifying a distinctive maladaptive antisocial pathway that may be included in the category of delinquency.

Serious Psychopathology

The fourth category of children and adolescents accounts for a very small portion of child and adolescent fire behavior. This category includes children who set fires as a result of extreme psychopathology including compulsive behaviors and/or psychotic ideation that may be specifically related to the firesetting (17,61). The DSM-IV diagnosis of pyromania represents another dimension of this category that is also extremely rare in children. Pyromania describes fire behavior that is deliberate, purposeful, involving an obsession with fire, with children showing tension or affective excitement before the act, and pleasure or gratification during the act (62).

Fire-Specific Variables

The modest body of empirical research over the last 30 years has converged to emphasize the critical role of fire-specific variables in the classification of firesetters. A treatment outcome study from 2006 examined recidivism at one-year follow-up among 48 juvenile firesetters. Findings supported the view that children who persist in lighting fires show a wider range of fire involvement and more intense fascination with fire at the start of treatment. Recidivists had a higher frequency of match play and more firesetting incidents including a greater involvement in fire-related acts such as hiding matches or lighters and pulling fire alarms. Repeat firesetters also demonstrated heightened curiosity, personal interest in fire, and fire

attraction, as well as more externalizing behaviors (22).

A more recent analysis of firesetters 4 to 17 has yielded 3 clusters which combine multiple factors from the ecologic model with a focus on fire-specific variables. The three clusters are termed as conventional limited (CL), home instability (HI), moderate and multi-problem (MP) risk. Firesetting behavior in the conventional limited category is distinguished by a relatively low fire interest or curiosity, but combined with: (1) a relatively low number of firesetting incidences, (2) a relatively late age of firesetting onset and child mental health contact, (3) the least varied range of ignition sources and target, (4) the highest percentage expressing remorse, and (5) the lowest percentage endorsing antisocial motivation. These children also had the most contact with their biologic parents.

In contrast, the home instability–moderate cluster is characterized by relatively larger number of firesetting incidents, greater fire interest and curiosity, and more varied ignition sources and targets when compared with conventional limited firesetters. There was a higher proportion of antisocial motivation and less expressed remorse in this group. This group was also characterized by less parental involvement, the highest percentage of abuse exposure, and the greatest number of children in care of a children's welfare agency, as well as more difficulties (when compared with CL) for social relationships, attention and externalizing behaviors. Of note, the abuse exposures were the highest in this group when compared with all other categories.

Finally, the multi-problem risk group engaged in the overall highest number of firesetting incidents and had the youngest firesetting onset. They demonstrated high levels of fire interest and curiosity and had, among all groups, the most varied number of ignition sources and targets. In addition, this cluster was distinguished from the other two groups by the highest levels of social skill deficits, attentional difficulties, and externalizing behaviors. Interestingly, none of these youth were placed in care of a child welfare agency (although many had been referred) and, as noted above, this category had a lower level of abuse than the home instability group, but higher levels than the conventional limited group. Like the home instability group, the multi-risk group included few youth expressing remorse and greater number of youth with antisocial motivation (63).

ASSESSMENT

Prior to any evaluation of children's fire behavior it must be determined whether the purpose is to assess for treatment or to evaluate the risk of recidivism. There is currently little empirical support for the predictive validity of risk categories as they primarily rely upon the clinical expertise of individual practitioners (16,50,62). The ecologic model and the expertise of experienced practitioners, when combined with training in a thorough assessment protocol, are currently considered the standard of

practice for juvenile firesetter risk assessment. A good example of a thorough protocol would be the FRAT-Y Firesetting Risk Assessment Tool for Youth (64). In some states, risk assessments are requested by the courts to inform placement decisions. Such assessments can provide useful information that can guide treatment decisions and should be obtained prior to beginning treatment. In this section, we will restrict our discussion to treatment assessment using the ecologic–transactional model (65).

Information from referral sources and other outside agencies should be obtained prior to the assessment. Many referrals of children who have set fires are initially screened through the fire department or juvenile diversion programs. This interdisciplinary involvement has influenced the development of standardized screening measures, which in some states are widely used, but have yet to be validated (66). Examples of screenings/assessments are the Oregon Screening Tool, Maine Screening Tool, and the Federal Emergency Management Tool (66). The evaluating clinician can identify whether any screening measures are being administered in their region and follow up by requesting a copy of the measure prior to interviewing the child and the family. These screenings provide a basis for further inquiry into the nature of the firesetting incident and the existence of other behavior problems or delinquent activities at home or school. In addition, there may be a written report summarizing the fire investigation that rests with the fire department or a law enforcement agency. Reviewing this “cause and origin” or fire/arson investigation report (55,67) from the fire department can be particularly helpful with preteens and adolescents, who may be less inclined to be truthful regarding the nature of the incident. The report can provide a foundation for confronting the child with inconsistencies in their narrative and promote accountability as well as provide a basis for assessment of the complexity of the fire behavior (e.g., the use of accelerants, covert hiding of materials, deliberation). Finally, prior to the assessment, older children, adolescents, and parents must be informed about the limits of confidentiality and protections of disclosure within the larger community or juvenile justice system, particularly whether or not disclosure of firesetting may lead to criminal justice involvement.

Once these initial steps are taken, child assessment should proceed with a thorough understanding of firesetting behavior both past and present. Recognizing when fire behavior deviates from normative development requires an understanding of the child’s behaviors, cognitions, and emotions surrounding the firesetting incident, including what was used to start the fire, the location, if others were present, the child’s response to the event and how the fire was extinguished (27,61,67). Several preliminary questions may precede more structured assessment methods. For example, children are generally asked if they have ever played with matches or lighters and if they have ever “set a fire,” or “set a fire in order to burn something” (see Wilcox and Kolko (67) for a more thorough discussion of

unstructured interview techniques).

Prior to the assessment, the evaluator should consider modifying the interview format to match the developmental level of the child. In general, preschool-aged children will require visual stimuli (e.g., "Play Safe; Be Safe" drawings, empty match boxes) (68) and an emphasis on obtaining a simple narrative of the sequence of events around the fire incident, with minimal focus on motivational states as these are difficult for most preschool-aged children to report. Elementary school–aged children, particularly those with learning disabilities and attentional/concentration difficulties can benefit from these methods and techniques as well. Wilcox and Kolko (67) noted several questions that capture important nuances of the child's degree of planning and learning from the experience that may be particularly helpful for elementary school–aged children ("How did you get the idea to start the fire?" "What did you think would happen when you actually started the fire?" "Did the fire act the way you thought it would?" "Did you learn anything from what happened?"). The latter questions can be helpful in linking assessment to educational or psychosocial interventions. With adolescents, the interviewer may need to confront denial or avoidance directly by using collateral reports and discussion of the context and purpose of the interview in the larger system (69). Self-monitoring techniques have been popular among evaluators in helping children to report accurately on thoughts, feelings, and behavior related to the firesetting incident; however, they may be beneficial in the interview process as well (70). One study has simplified this method using vignettes to introduce the relationship among thoughts, feelings, and actions (16), which can help children become acquainted with the concepts before applying them to their own firesetting incidents. One area that has received very little attention is the assessment of fire behavior among developmentally disabled populations. As with younger children, the interview will likely focus less on more complex motivation and more on curiosity or fascination, use more visual cues and prompts, and include more inquiry on fire safety skills awareness, as well as family and ecologic factors that may be contributing to lapses in supervision or monitoring.

Multi-source (parent, child, and teacher report) and multi-method assessment protocols are recommended across at least two settings (e.g., home and school environments) to identify the scope and intensity of firesetting or associated behavioral disturbance. Some instruments have been validated in general clinical populations, but clinical utility in firesetting populations is less well established. Other fire-specific instruments have been developed for research purposes, but have not been as well examined in clinical populations.

Both structured interviews and behavioral rating scales have been developed for use with juvenile firesetters. These tools include questions about how materials were obtained, the site of fire, type of property damage, fire competence, exposure to fire models, fire involvement (hiding of matches/lighters), and curiosity/fascination with fire (19). The domain of learning and exposure relates to how the child acquired

exposure and knowledge of fire in his/her family. Attempts should be made to identify (1) the current and past adult, sibling, or peer models of fire behavior, (2) the age of exposure to fire and to models of fire safety, (3) the nature of the exposure (whether unsupervised, supervised, or guided with developmentally appropriate explanations), (4) the consistency of the caregiver or peer modeling, and caregiver supervision, and (5) child fire competence (knowledge) and fire safety skill (both child report and parental perception).

One important domain is that of fire competence, skill, and understanding. Firesetters (6 to 13 years old), when compared with non-firesetters with similar behavioral health profiles, have been shown to be more knowledgeable about types of things that burn, more curious, less fire competent (lacking in both fire safety skills awareness and an understanding of the properties of fire). In addition, exposure to fire activities in the home and community should also be assessed (e.g., individuals in home who smoke or have been burned, fires in neighborhood, or friends who smoke) (18).

Assessment of problems in family functioning is the next important domain for assessment. This may include an evaluation of the quality of the parent–child relationship/communication, the degree of parental involvement, warmth and nurturance, disciplinary practices, as well as parental psychiatric distress and exposure to stressful life events. Generally, the parenting process can be organized into three dimensions: (1) motivation (parental belief systems including norms, values, and parent goals), (2) parental monitoring, or the tracking and structuring of the child's activities, social ecology or environments, and (3) behavior management (the parent's active attempt to shape positive outcomes by using incentives, reinforcement, limit-setting, and negotiation). Parental monitoring is thought to be the common denominator within this process and is associated strongly with both parenting practices and measures of the parenting relationship/communication. In this way, parental monitoring may act as a protective factor for children living in high-risk settings and can provide a foundation for brief interventions for child and adolescent problem behavior and child injury prevention (71). Future research should examine the application of these dimensions of parenting as they pertain specifically to fire behavior.

The FRI contains sections assessing parenting regarding both fire-specific issues and more general concerns. Fire-specific domains in the FRI include parental fire awareness (parental safety instruction in the home, fire safety instruction in the home, practicing fire-escape drills), as well as general parenting practices (use of mild vs. harsh punishment, parental supervision). In Table 5.1.4.1, we list several measures of family functioning and stressful life events that are used in the assessment of disruptive behavior disorders and may be useful in the assessment of family functioning among juvenile firesetters specifically (18). Assessment may also include parental psychiatric history/distress, as this is more commonly found among

firesetters when compared with non-firesetters (24).

TABLE 5.1.4.1

ASSESSMENT TOOLS FOR USE IN EVALUATION OF JUVENILE FIRESETTING[a]

Name of Measure	Brief Description	Reporter
The Firesetting Incident Analysis—Parent and Child Version[b] (FIA-P, FIA-C) (60)	Structured interview that obtains information regarding specific fire incidents	Parent and Child Report
The Firesetting Risk Interview[b] (FRI) (14)	Structured interview used to assess several domains related to fire involvement	Parent Report
Children's Firesetting Inventory[b] (CFI) (15)	Structured interview used to assess several domains related to fire involvement, administered to children	Child Report
Fire Interest Questionnaire[b] (63)	Structured interview used to assess several domains related to fire involvement, administered to children	Parent and Child Report
Child Behavior Checklist (CBCL) (61)	Rating scale used to assess several dimensions of children's emotional and behavioral functioning	Parent Report (Teacher Report Form also available)
IOWA/Conners (IOWA/C) (62)	Rating scale used to determine the presence of hyperactivity, impulsivity, and inattention in children	Parent Report
Children's Hostility Inventory (CHI) (63) and Children's Inventory of Anger (CHIA) (64)	Questionnaires used to assess aggression and hostility among children	Parent or Child Report
Children's Depression Inventory (CDI) (65)	Brief rating scale used to measure children's level of depressive symptoms	Child Report
Trauma Symptom Checklist for Children (TSCC) (66)	Rating scale measuring psychological distress and related symptomology	Child Report
The Parent–Child Conflict Tactics Scales (CTSPC) (67)	Assesses parental disciplinary strategies during child conflicts (nonviolent discipline, psychological aggression, physical assault)	Parent Report
Parent–Child Relationship Inventory (PCRI) (68)	Assesses parent–child communication strategies	Parent Report

[a]This table is not an exhaustive battery, but reflects an array of tools that have been clinically useful and often incorporated into empirical investigations of juvenile firesetting. For a more extensive review of measures, see Kolko DJ, Swenson CC: *Assessing and Treating Physically Abused Children and Their Families*. Thousand Oaks, CA, Sage Publications, 2002.

[b]These instruments can be solicited from the first author upon request.

Finally, the evaluator should be sure to obtain information regarding the range of delinquent behaviors that may be associated with firesetting behavior. In particular, cruelty to animals, violence toward others or property, truancy, running away, breaking and entering, and court involvement may increase risk for future delinquency and firesetting. A history of exposure to domestic violence and early modeling of paternal cruelty toward animals are also activities (37) that may be associated with a higher risk of maladaptive outcomes (e.g., delinquency and court

involvement).

TREATMENT

A thorough assessment of fire behavior guided by the ecologic–transactional model yields information that corresponds with skill-based, multimodal approaches that can stand alone or be used to supplement ongoing treatment interventions such as fire safety skills training (FSST), self-monitoring, parent–child communication, parental psychoeducation, promoting emotion regulation and alternative coping strategies, and restitution for damages (2,16,72,73). Treatment outcome studies for juvenile firesetting are few and yield limited, if promising, results. Samples are heterogeneous, making it difficult to identify whether subgroups based on severity or breadth of dysfunction would benefit from a specific element of treatment (e.g., children vs. adolescents; match players vs. repeat firesetters). Treatment protocols are also varied, making it difficult to identify specific elements of treatment that are more or less effective. There is a relative lack of randomized controlled studies when compared with other areas of child behavioral health (e.g., depression, aggression). Reductions in recidivism may reflect change over time following treatment, additional behavioral health treatment for other problems, or change due to a nonspecific factor in fire treatment. Yet there is accumulating evidence that FSST and cognitive behavioral therapy (CBT) are promising interventions, particularly when combined or delivered in a collaborative format (2,3). FSST has been shown to be more effective than a general discussion of the fire incident with inpatient children aged 4 to 8 years (33). Another study compared one-time fire safety discussion/pamphlet with a combined educational and home-based psychosocial intervention delivered by fire educators (satiation, response cost, self-monitoring/graphing of antecedents, and associated emotions and cognitions). Of the children, 67% demonstrated improved fire behavior, with 42% setting no fires in the 12 months following the intervention. Thirty percent of the families were not assessed because they could not be located. In this study, even the very brief fire safety intervention had an impact on reducing recidivism, with a one-time pamphlet shown to effectively reduce repeated fire activity (2).

FSE remains a core component of most interventions for juvenile firesetters. One-classroom-style FSE program included live tours of a burn unit, a curriculum on fire knowledge and safety awareness, and lectures from returning veterans of the program. There are innovative programs being developed that involve collaboration with fire departments (74) and more standard group treatment models for disruptive behaviors. In fact, there appears to be a variety of fire-specific psychosocial interventions and/or safety education/skills training that can reduce recidivism from 6 months up to 2-year follow-up (2,33). Given findings that a significant percentage of firesetters will repeat if untreated (19), it seems imperative that intervention efforts

be early and swift.

The most rigorous outcome study to date shows that when FSST and brief cognitive behavioral treatment (average number of sessions was 5.5) are administered in a highly standardized format, they can be superior to a one-time pamphlet and safety contract (75), although not superior to each other. This study set the standard for multimodal and collaborative treatment of juvenile firesetters by integrating self-monitoring techniques (identifying the personal and environmental context of the firesetting) into a treatment including relaxation, cognitive restructuring, assertion skills training, problem solving, and parental skills training (selective attention, reinforcement, contingency management) (3).

A subsequent small outcome study of firesetting treatment outcome of 48 youth compared FSE, CBT and FHV (a single-informational firefighter home visit). This study suggested that FHV may be less effective for families with heightened dysfunction. Interestingly, FSE appeared more effective with children who had greater fire safety knowledge. These exploratory findings suggest the potential benefit of systematically examining the characteristics of youth who respond to treatment, to better match firesetting youth with a potentially successful treatment (22).

Influenced by Kolko's work, other innovative and cost-effective fire-specific interventions for parents and families have been developed that include clearly defined treatment objectives that can lead to standardization of administration and some evaluation of recidivism. One intervention effort has offered classes to 247 families of firesetters from 2000 to 2005 through the Washington County Fire Academy (57), with estimates of 3% to 6% recidivism. These classes meet two times per week for 6 weeks with parents and children attending concordant programs. Children receive FSE with their peers, while parents meet with one another and identify the ecologic factors contributing to their child's firesetting (Oregon "Cycles" Model) (57), learn myths and facts about firesetting behavior, are instructed in contingency management, positive praise techniques and response–cost techniques, and identify areas of psychopathology that may need attention (e.g., untreated ADHD, parental conflict, or other family stressors).

Similarly, in a treatment study through Bradley Hospital in Rhode Island, families of firesetters receive 4 weeks of 1.5-hour concordant sessions. Children meet with their peers prior to working directly with their parents in Multiple Family Group Intervention (MFGT). This model focuses on improving the quality of family communication about fire and uses group and individual exercises (e.g., affect identification, self-monitoring) to facilitate children's experience of mastery over fire behavior. Children learned to identify and monitor both emotions and thoughts associated with fire behavior and identify coping strategies through four exercises: group discussion designed to destigmatize fire communication, vignette and game activities, review of firesetting incidents, and coping strategy contracts. These strategies were then refined with children and parents in an MFGT session. Parents

received psychoeducation about the ecologic model and cyclical nature of firesetting (57) combined with experiential discussion related to fire communication in the family (e.g., how parents first learned about the fire behavior, the quality of the family communication around fire behavior/safety, the parent's history of modeling safe fire behavior, and development of a home fire safety checklist and escape plan).

In a third example developed in Ontario, Canada, and operating for over 20 years, fire safety education and parent–child intervention are delivered simultaneously by a trained local behavioral health clinician (76). The content of the protocol is described in a detailed manual with fire-specific exercises and worksheets for caregivers and children. The protocol is conducted in five sessions (total of 7.5 hours) and includes modules on fire safety (attitudes, high-risk situations, and behaviors) in and out of the home, rewarding fire safety behavior, parental supervision and monitoring access to ignition materials, understanding antecedents to fire involvement, and teaching a systematic approach to consequences of future fire involvement. Follow-up of over 200 families receiving the intervention indicate that approximately 75% had no further fire involvement over 1 to 2 years (77). Interestingly, this is the only program to evaluate the adoption and implementation of the protocol through a survey of approximately 700 community professionals trained over 8 years. Findings indicated that although 89% of the clinicians made a commitment to use the protocol, only 29% implemented the protocol on a routine basis. Factors such as the compatibility of the protocol with existing practice, ease of use, and adopter self-efficacy may have influenced implementation (78).

Remarkably, there has been little empirical evaluation of the specific treatment needs of preschool or adolescent firesetters, given that preschool fire behavior may be associated with some of the greatest danger for loss of life and adolescent fire behavior can lead to the most costly treatments (i.e., residential and juvenile justice incarceration). Existing FSE program curriculums that are directed toward preschoolers can be incorporated into daycare programming for children (68,74). Parental participation is critical to any systematic approach to treatment of preschoolers and two of the four psychosocial interventions previously described have been used with preschoolers (72,79).

Many adolescents come to the attention of behavioral health providers through the criminal justice system, and may be engaging in a broad range of delinquent behaviors. Some may be charged with arson and then referred to intervention programs that specialize in working with delinquent adolescents engaging in fire behavior. Several models have been developed, ranging from those offering individually supervised restitution or community service activities to more structured fire safety and CBT skill-based group interventions (42). These court diversion intervention programs designed specifically for children convicted of arson have yet to be evaluated using more rigorous experimental designs, although some conform to best practice guidelines for youth offender programs established by the Office of

Juvenile Justice and Delinquency Prevention programs (42). Multisystemic therapy has also shown some promise in the treatment of serious juvenile offenders, some of which included those teens 13.7 years old charged with arson (80). However, many of the studies and treatment models previously reviewed in this chapter included children referred by the court system and may have been influential in reducing or eliminating dangerous fire behavior among these court-referred youth. For group or residential treatments, there is a potential for negative impact for modestly deviant or delinquent adolescents, if these teens are exposed to deviant older youth. Such deviant peer exposure effects may detract from the overall positive impact of the intervention and are in need of rigorous evaluation (81).

There have been calls for clearer standards of care in residential settings for evaluation and placement of firesetters (74). Recently, one study comparing 17 adolescent firesetters in residential treatment with 30 adolescents with first-time fire histories demonstrated no differences in psychopathology, delinquent personality characteristics, and surprisingly, fire-specific characteristics (e.g., number of fires set, use of accelerants, location of the fire, injuries caused by the fire). Instead, a greater proportion of residential teens came from single-parent homes and had higher scores of aggression (82), suggesting that lack of safety, supervision, and monitoring in the home environment, coupled with aggressive behavior, may be the primary factors leading to out-of-home placement. There has been a call for better integration of fire-specific treatment with residential facilities, making FSST a treatment objective that is actively monitored in clinical care meetings throughout placement along with coordination of resources outside of the residential program as necessary to provide FSST (83).

The treatment of specific populations, such as children diagnosed with mental retardation or significant learning and communication limitations (e.g., autism, impaired attention/concentration, reading and writing challenges, limited reasoning capacities) has received little attention. There is need for specialized delivery of FSST or CBT techniques for these groups. One case study describes the use of a multicomponent behavioral treatment approach with a hospitalized 6-year-old boy with developmentally disabilities. Treatment included negative practice with correction from his mother, token reinforcement, and routine discipline instruction (84). Another study used a virtual reality computer game to teach fire safety skills to children diagnosed with fetal alcohol syndrome. The games were administered without direct assistance from parents or observers (85). We have found the use of educational videotapes and testimonials useful for children with limited cognitive abilities who are resistant to FSST. We have adapted and simplified techniques by avoiding discussions of motivations of firesetting or past experiences (beyond the initial assessment) and adapting workbooks and curriculum available online to create structured learning sequences. The sequences maintain a focus on understanding “how things work” and reinforce a sense of mastery and competence with fire for

these youngsters.

Children repeatedly lighting matches to satiate interest under the supervision of an adult is one of the earliest behavioral interventions reported to be effective in decreasing a child's interest in fire and firesetting behaviors (86). This practice, however, is rarely encouraged, due to the risks of the potential negative effects of modeling fire behavior and reports of the large number of sessions required to be effective. Given the prominent association of curiosity or fascination and psychopathology, further development of behavioral interventions that target fire fascination is warranted, perhaps through the specification of overt or covert sensitization techniques (i.e., use of stories, narratives, testimonials, or visual stimuli to discourage contact with fire). If such programs were systematically evaluated and included measures related to specific treatment components, we may better understand the cognitive and behavioral change processes that make both FSE and psychosocial treatment effective.

As noted earlier, FSE delivered in a classroom, combined with experiential format, has been shown to reduce recidivism significantly (87), and FSST delivered to children individually has been shown to be as effective as CBT (88). The modality of delivering of FSE, however, may differ considerably between local communities and service providers. Guidelines for FSE are broad, and the availability of FSE intervention will depend upon community resources. Thus, it is incumbent upon the behavioral health clinician to have some knowledge of exactly what is being delivered in the community to facilitate clinical treatment objectives, to avoid duplication of services, and to assess and monitor the child's generalization of fire safety skills. FSE can include the following topics: fire facts (e.g., fuel, how fire grows/spreads and how is it extinguished/controlled, smoke inhalation dangers), fire safety awareness (i.e., “matches are tools and not toys,” safe distance, home fire safety “projects” such as identifying common fire safety hazards in the home or collecting information regarding the causes and consequences of fire in the community), fire survival (e.g., smoke detectors, home fire escape plan and strategies, “stop, drop, and roll”), fire consequences (potential criminal justice involvement, burns, damages to community both direct and indirect) (15,28).

Fire behavior crosses over the boundaries of several disciplines (fire service, juvenile justice, behavioral health, pediatric injury prevention, and child protection), with many of these disciplines using public health prevention education techniques (89). Basic FSE principles (stop, drop, and roll; use of 911; and match/lighter safety slogans) are delivered in many elementary school classrooms around the country. Unfortunately, the efficacy of these education programs has yet to be established. For example, many children do not effectively generalize simple fire safety instruction following a single classroom exposure. Two examples of preschool prevention programs are the “Learn Not to Burn Program” and the “Play Safe; Be Safe” curricula. A middle school curriculum has been designed (72). Many of the tools and

exercises in these prevention education curricula can be adapted for use in clinical therapies with individuals, families, or groups.

Psychopharmacologic techniques for treatment of juvenile firesetting populations have largely been neglected in the empirical literature. To date, no specific medications are used to treat firesetting behavior per se. Instead, juvenile firesetters are treated for associated difficulties such as disruptive behavior problems, ADHD, or internalizing distress. In many cases, and as suggested by the ecologic–transactional model, risk for future firesetting will decrease secondary to the improvement of associated psychological and behavioral difficulties, as these factors increase vulnerability for repeated fire activity. Improvement in these areas, in turn, provides opportunity for more adaptive developmental outcomes.

As noted earlier, juvenile arson is not merely a clinical concern, but a public health and safety problem of large proportions. Inter-agency collaborative relationships among city departments, community-based organizations, city residents, and state law enforcement and fire prevention agencies are needed to develop multilayered community prevention programs (90). In Detroit (a metropolitan area of over 500,000), one such collaborative effort successfully reduced the incidence of fires set in the community on Halloween night from record numbers of fires set in 1984 (810 fires over a 3-day period) to levels consistent with incidence at other times of the year. Many of these fires were suspected to be set by youth; the intervention included after-school and evening programs as well as a curfew to monitor more effectively children's whereabouts and limit access to dumpsters and abandoned buildings. Moreover, the intervention included the deployment of public safety personnel, the elimination of arson targets through community cleanup, volunteer mobilization and training, public media and communications campaigns, and prohibitions on the safe use of fuel (90).

CONCLUSION

Fire behavior in children and adolescents is a problem of surprising scope, carrying with it the potential for death, injury, and property loss of striking proportions. The problem spans all ages, is particularly prevalent among children in psychiatric settings, and often is not identified unless the clinician specifically asks about experiences with firesetting and fire play. The complexity of the development of juvenile firesetting behavior is best captured by an ecologic–transactional model that includes factors related to individual functioning, parental processes, peer socialization, neighborhood and school safety, and cultural socialization. Assessment should be fire specific, but correspond with the best practices in the assessment and treatment of disruptive behavior disorders (multimodel, parent and child report, developmentally sensitive methods), internalizing disorders, and mixed internalizing/externalizing disorders. When child and adolescent fire behavior is

associated with externalizing and internalizing disorders, families may benefit from promising collaborative treatment programs combining FSE with cognitive–behavioral treatment and/or parent–child treatments. While children without associated emotional disorders will likely benefit from FSE alone, some children with behavioral disorders may also see a reduction in repeat fire behavior, without any additional psychosocial treatment.

ACKNOWLEDGMENT

This research was supported through grants from the Providence Mutual Fire Insurance Agency and the Shriner's Foundation. The authors are grateful to the contributions of Kristen Durbin, Lauren Mernick, Beth Hollander, James Leverone, LCMHC; Julie Lucier, Psy.D.; and Peter Gillen, Psy.D.

5.2 DEVELOPMENTAL DISORDERS

CHAPTER 5.2.1 ■ AUTISM SPECTRUM DISORDER

FRED R. VOLKMAR, GERRIT I. VAN SCHALKWYK, AND BRENT VAN DER WYK

DEFINITION

In Kanner's original (1) description of autism he felt that two features were essential for the diagnosis: autism and "resistance to change"—the latter category including literal troubles with change but also an "insistence on sameness" and the stereotyped mannerism and behaviors so frequently associated with autism in children. Various attempts were made to provide more formal guidelines and to clarify the early confusions, for example, about whether autism was a form of schizophrenia. By 1980, a sufficient body of work had accumulated to suggest that autism was a disorder in its own right and it was included as an official diagnosis for the first time in the ground-breaking Diagnostic and Statisical Manual (DSM)-III (2). That definition focused more on "infantile" autism, in so far as it did not really encompass an understanding of developmental change. Subsequent editions of DSM attempted to cope with this problem. DSM-III coined a new term "pervasive developmental disorder" for the class of conditions to which autism was assigned. The DSM-IV approach provided considerable flexibility in terms of coverage of the broad range of autism (over both age and developmental level) and also converged with the International Classification of Diseases (ICD)-10 approach (3). This convergence facilitated research and clinical work. In both DSM-IV and ICD-10 other disorders were recognized within the broader pervasive developmental disorder (PDD) category, for example, Asperger disorder and a subthreshold concept for individuals with some but not all features of autism or other formal diagnosis (4). These two approaches continued for nearly two decades. However, major changes were undertaken in DSM-5.

A number of overall changes were made in DSM-5, for example, relative to multiaxial classification and a move toward modifiers and specifications of severity as well as an emphasis on the use of existing diagnostic instruments to develop criteria (see Chapter 4.1). The term pervasive developmental disorder (as the overall term for the class of disorders) was replaced by autism spectrum disorder. A new disorder (social communication disorder [SCD]) was added. Asperger's, Rett's and other types recognized in DSM-IV were not identified. In contrast to the traditional grouping (as in DSM-IV) of criteria into social, communication, and behavioral problems (such as resistance to change), the social communication criteria were reduced in number and placed in a single category, with the requirement that all features should be met for the diagnosis to be made. The restricted and repetitive behaviors domain criteria were reduced in number (although a new feature related to hypo/hypersensitivity was added) and for this group two of

the four diagnostic features were required. The marked change in approach from DSM-IV was based on analysis of a large body of standardized data (5). The previous social and communication category is now monothetic (i.e., all features must be met) while the restricted behavior category remains polythetic, requiring evidence of symptoms in two of four symptom groupings; the respective and restricted behavior domain also includes a new (to DSM) symptom cluster reflecting sensory difficulties. A specification that symptoms must be present in early development enacted a universal onset criterion, with the caveat that problems may not manifest until social demands exceed limited capacities. Other innovations of the DSM-5 approach included the specification of modifiers (e.g., with catatonia) and levels of severity. A new diagnostic category, SCD, defined by difficulties in the social use of language was introduced.

Despite some clear advances (e.g., the change of name to autism spectrum disorder), other aspects of the DSM-5 approach have proven controversial (4). The rationale for the new SCD remains unclear with a miniscule body of supporting research (6). Probably most importantly, as the draft DSM-5 criteria began to appear, a series of studies (7) have fairly consistently shown problems with the DSM-5 approach particularly relative to higher cognitively functioning individuals (8) and very young children (9). This result has potentially serious implications for service eligibility and as a result, a final decision was made to add the criterion to the new DSM-5 approach that allows individuals with previously well-established diagnoses (under DSM-IV and ICD-10) to keep them. Effectively, this creates two approaches—continuing the old one and adding a new one that appears to be more restricted for newly diagnosed cases. In addition, the implications of the Research Domain Criteria (R-DOC) approach and ICD-11 remain unclear (see Chapter 4.7). The various approaches to diagnosis of autism/autism spectrum disorder (ASD) are summarized in Table 5.2.1.1.

HISTORY

Following Kraepelin's description of dementia praecox in adolescents, the concept was extended to children and the terms childhood schizophrenia and/or childhood psychosis became blanket terms for all apparent severe psychiatric disturbance in children (apart from what was then recognized as intellectual disability) (see Chapter 5.2.2). These early assumptions of continuity with adult-onset psychotic disorder began to describe unique constellations of difficulty of childhood onset. Kanner's classic description of the syndrome of early infantile autism exemplifies this approach (1). His presentation of 11 cases of "inborn disturbance of affective contact" was a landmark in the field. He emphasized two core features for diagnosis: (1) autism (a marked lack of interest in others) and (2) insistence on sameness/resistance to change (this included both literal insistence on rigid

adherence to routines and difficulties with change as well as the motor mannerisms and stereotyped behaviors). Kanner believed these problems were of early onset—from the beginning of life or in the first year or two of life. Kanner noted many of the clinical features that continue to be recognized in classic autism, for example, mutism or echolalia, marked communication problems, and so forth. One year after Kanner's description Hans Asperger (10) also reported a small series of cases—all boys who had marked social difficulties along with unusual circumscribed interests but relatively good verbal abilities. Asperger disorder was officially recognized in DSM-IV and ICD-10 for the first time and work on it increased dramatically (11) with various lines of research suggesting the validity of this concept as distinct from autism (12). In important ways, the issues of making discriminations among various forms of social disability remain an open topic for research, particularly given the genetic work suggesting involvement of a number of genes and a growing awareness of the potentially broader spectrum of heritable social vulnerabilities (Table 5.2.1.2).

TABLE 5.2.1.1

ICD-10 CRITERIA FOR CHILDHOOD AUTISM (F84.0)

A. Abnormal or impaired development is evident before the age of 3 years in at least one of the following areas:
   1. Receptive or expressive language as used in social communication
   2. The development of selective social attachments or of reciprocal social interaction; functional or symbolic play
B. A total of at least six symptoms from (1), (2), and (3) must be present, with at least two from (1) and at least one from each of (2) and (3).
   1. Qualitative impairments in social interaction, as manifested by at least two of the following areas:
      a. Failure adequately to use eye-to-eye gaze/facial expression, body postures, and gestures to regulate social interaction
      b. Failure to develop (in a manner appropriate to mental age, and despite ample opportunities) peer relationships that involve a mutual sharing of interests, activities, and emotions
      c. Lack of socioemotional reciprocity as shown by an impaired or deviant response to other people's emotions; or lack of modulation of behavior according to social context; or a weak integration of social, emotional, and communicative behaviors
      d. Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., a lack of showing, bringing, or pointing out to other people objects of interest to the individual)
   2. Qualitative abnormalities in communication, as manifested by at least one of the following areas:
      a. Delay in, or total lack of, development of spoken language that is not accompanied by an attempt to compensate through the use of gestures or mime as an alternative mode of communication (often preceded by a lack of communicative babbling)
      b. Relative failure to initiate or sustain conversational interchange (at whatever level of language skill is present), in which there is reciprocal responsiveness to the communications of the other person
      c. Stereotyped and repetitive use of language or idiosyncratic use of words or phrases
      d. Lack of varied spontaneous make-believe play or (when young) social imitative play
   3. Restricted, repetitive, and stereotyped patterns of behavior, interests, and activities, as manifested by at least one of the following:
      a. An encompassing preoccupation with one or more stereotyped and restricted patterns of

interest that are abnormal in content or focus; or one or more interests that are abnormal in their intensity and circumscribed nature, though not in their content or focus
   b. Apparently compulsive adherence to specific, nonfunctional routines or rituals
   c. Stereotyped and repetitive motor mannerisms that involve either hand or finger snapping, or twisting or complex whole-body movements
   d. Preoccupations with part objects or nonfunctional elements of play materials (such as their odor, the feel of their surface, or the noise or vibration they generate)

C. The clinical picture is not attributable to the other varieties of pervasive developmental disorders; specific development disorder of receptive language (F80.2) with secondary socioemotional problems, reactive attachment disorder (F94.1), or disinhibited attachment disorder (F94.2); intellectual disability (F70–F72) with some associated emotional or behavioral disorders; schizophrenia (F20) of unusually early onset; and Rett syndrome (F84.12).

EPIDEMIOLOGY

It is now the case that hundreds of studies of the epidemiology of ASD/autism have been completed around the world—as summarized elsewhere (Table 5.2.1.3) (13). Several issues complicate the interrelation of results obtained and comparisons across studies. These include differences in diagnosis approach (e.g., school vs. clinical data), methods of ascertainment, potential problems of undersamplings relative to specific populations, and so forth. The problem of diagnostic substitution is significant (14), for example, in the United States in particular a single label is typically used for identifying students for service eligibility and, as awareness of autism has increased, schools and parents may be more likely to use this label for service eligibility thus inflating estimates compared if such data, rather than direct child assessment, are used to establish “caseness.” Conversely there are also data suggesting that in some populations, for example, with impoverished students in inner cities, underdiagnosis may be common (15). Overall, however, it appears that for ASD an estimate of 6.6 children per 1,000 is reasonable (13). What is often assumed to be a real secular increase over time most likely reflects changes in diagnostic concepts, increased awareness of the range of ASD, and availability of services. It does appear that boys are three to four times more likely to have ASD than girls, although females can have subtler social difficulties (16).

ETIOLOGY

In the years following Kanner’s initial description considerable debate centered on the pathogenesis of autism. Kanner’s observation of high levels of occupational success in parents led some to assume a role of psychological factors in the etiology of the condition. Additional complexity arose given the early confusion of autism with childhood schizophrenia (17). During the 1970s it became clear that autism was a distinct disorder in its own right. Longitudinal studies suggested a high risk for onset of epilepsy particularly in adolescence (18) as well as a very strong role of genetic factors given the higher concordance of autism in identical, as compared to

same-sex fraternal twins (19). By 1980, when infantile autism was first recognized as an official diagnosis (2) considerable evidence suggested that it was a highly genetic and strongly brain-based disorder.

In the decades subsequent to its official recognition, research on ASD had expanded dramatically. Much work has centered on understanding the neurobiologic basis of the disorder as well as potential genetic contributions; increasing efforts have been made to understand the core "autism" aspect, that is, the marked social learning problems that characterize autism. Different approaches have been used to understand the social brain in autism.

In 1990, Brothers (20) published a seminal article arguing that a small set of regions comprised the "social brain" dedicated to processing socially relevant information about conspecifics (21). These regions included the amygdala, the orbitofrontal cortex, and the ventral and lateral temporal cortex (see Table 5.2.1.4). The theory was supported by evidence from nonhuman primate electrophysiology and human neuropsychology (20). This theory was highly influential in guiding early human studies in the emerging discipline of neuroimaging. Paralleling the growth of neuroimaging, there was an increasing appreciation of ASD as both a brain disorder and as a disorder of social cognition (22). Thus, it was natural that many early neuroimaging studies in ASD focused on the neural correlates of social cognition (23–25). Indeed, although ASD research has broadened substantially, the study of the neural correlates of social function continues to be the dominant topic and has centered on several areas.

TABLE 5.2.1.2

EVOLUTION OF DIAGNOSITC CONCEPTS

Source/Term	Summary	Comment/Critique
DeSanctis (1906) Dementia praecox	Childhood schizophrenia, rapid extension of Kraepelin's original concept	Childhood psychosis became a blanket term; in reality, schizophrenia onset before adolescence is rare
Heller (1906) Dementia infantilis	Late-onset autism with marked regression in previously normal child	Recognized in DSM-IV and ICD-10 as childhood disintegrative disorder
Kanner (1943) Early infantile autism	The classic description of autism. "Autism" and "resistance to change" cardinal features	Concept has evolved over time. Early work began to show strong brain and genetic basis and need for structured treatment
Asperger (1944) Autistic psychopathy/autistic personality disorder	Marked social difficulties and motor problems but good verbal	Included in DSM-IV and ICD-10 but definition controversial, not included in DSM-5, often associated with unusual IQ profiles (better verbal than nonverbal skills)

	skills, marked circumscribed interests	
DSM-III (1980) Infantile autism development	First official recognition, included in new class of disorder “pervasive developmental disorders”	Definition more appropriate to younger and more impaired case
DSM-III-R (1987) Autistic disorder	More developmentally oriented definition, polythetic criteria grouped in three categories	Definition probably overly broad, attempt to have developmental orientation a plus
DSM-IV/ICD-10 (1994/1993) Autistic disorder	Definition finalized in large field trial that brought convergence of DSM and ICD definitions, included another disorder such as Asperger’s	Inclusion of new categories somewhat controversial Two decades of diagnostic stability and consistency of the two major definitions advanced research, polythetic with continued use of three categories of disturbance, many (<2,000) combinations of criteria could produce diagnosis, social items more heavily weighed
DSM-5 (2014) Autism spectrum disorder	Better term for condition, based on data from structured diagnostic instruments	Limited field trial data, definition more focused on “classic” cases with higher cognitive functioning individuals and very young less likely to get label. Social communication criteria (all must be met) and at least 2 of 4 resistance to change criteria. Potential for specification of severity and use of some modifiers, for example, autism with catatonia

Face processing has high face validity in tapping into the core social cognition deficits associated with autism (26) and can readily be studied using different approaches. Face processing as a developmental phenomenon in normative development has been extensively studied and has become one of the best studied areas in the cognitive neuroscience of ASD. Neuroimaging approaches rely heavily on the *method of difference, that is, a contrast must be made relative to some* control process to serve as the contrast. This question is a key component of study design and often a source of methodologic variability between studies and labs. For example, some studies consider face processing relative to the processing of nonface stimuli such as complex objects or scrambled faces. One early study that used a simple contrast between faces and objects found hypoactivation in the fusiform gyrus in individuals with ASD relative to typical controls (25); this area is thought to be a key component of the face-processing network in typically developing individuals (27). These results supported the idea that social cognition problems in ASD may be due to poor activation of this key region. This finding has been generally confirmed by further work (for a review, see (28)), but the dysfunction may not reflect a general

processing deficit, rather some combination of task complexity and attention (29). Table 5.2.1.4 summarizes some of the regions of interest relative to the social brain in autism.

TABLE 5.2.1.3

SELECTED EPIDEMIOLOGIC STUDIES OF AUTISM

Study	Location	Diagnostic Criteria	Prevalence/10,000	Gender Ratio (M:F)
Lotter (1966)	UK	Rating scale	4.1	2.6
Bohman et al. (1983)	Sweden	Rutter criteria	5.6	1.6
Ritvo et al. (1989)	US	DSM-III	2.47	3.73
Gillberg et al. (1991)	Sweden	DSM-III-R	9.5	2.7
Baird et al. (2000)	UK	ICD-10	30.8	15.7
Chakrabarti and Fombonne (2005)	UK	ICD-10 DSM-IV	22.0	3.8
Fombonne et al. (2006)	Canada	DSM-IV	5.7	21.6
Parner et al. (2011)	Australia	DSM-IV/TR	4.4	39.3
Isakesn et al. (2011)	Norway	ICD-10 + ADI + ADOS	3.2	14
Kcocovscka et al. (2012)	Faroe Island	ICD-10 + DSM-IV	2	21
Parner et al. (2012)	Denmark	ICD-8, 9, 10	4.4	18.65

TABLE 5.2.1.4

BRAIN REGIONS POTENTIALLY INVOLVED IN AUTISM

Neural System	Areas	Comment/Function
Social perception system		Evolutionarily conserved and shared with other primates, refers to the initial stages in social information processing
	Superior temporal sulcus (STS)	Decoding of nonverbal social signals such as gaze direction and facial expression
	The fusiform gyrus (FFG)	Face processing
	Extrastriate body area (EBA) in lateral occipitotemporal cortex	Visual perception and recognition of the human body
	The amygdala and limbic system	Perception of emotional states and salient emotional experiences
	The orbitofrontal cortex (OFC) and ventrolateral prefrontal cortex (VLPFC)	Social reward and reinforcement
Mirror neuron system	The inferior frontal gyrus and the inferior parietal lobe (IPL)	An evolutionarily conserved system, plays an important role in action perception, understanding, and prediction
The mental		Probably unique to humans

state reasoning system		
	The medial prefrontal cortex (MPFC) and temporoparietal junction (TPJ)	Responsible for reasoning about others' thoughts

Other studies considered subtler aspects of face processing and processing of affective dimensions relative to nonaffective dimensions, operationalized as a contrast between emotional and neutral faces. An early finding along these lines identified lower activation in the limbic areas (23) in support of an amygdala theory of ASD (30). However, a finding of amygdala hypoactivation is not as consistently replicated in face-processing studies as other effects (28).

Other approaches have also been employed, using electroencephalogram EEG (31) as well as eye tracking (32). Differences in processing both faces and dynamic faces have been noted. Individuals with ASD also show slower event-related face processing (31). Similarly, differences in dynamic face processing using eye tracking have been observed with the earliest studies highlighting a tendency to focus on the lower versus upper part of the face (32). Thus, differences in brain activation may not be due to inherent processing differences but instead due to differences in stimulus intake (see Fig. 5.2.1.1) (33). Subsequent work has made it clear that these issues are complex but generally speaking there does appear to be important differences in the ways faces are processed in autism (34,35). Similar findings arise with respect to perception of biologic motion (36), affect perception, and so forth. This work has important limitations given variations in methods, samples, etc. but does suggest important areas for future work. The results have already been extended to use in high-risk samples (i.e., infant siblings) with interesting differences observed as early as 6 months (37).

Genetic studies of ASD have similarly increased dramatically—in scope, sophistication and complexity. A range of methods has been used since the earliest studies of twins suggested high heritability of the condition (38). Several findings are of note. Although in the past it was suggested that autism was associated with a host of medical conditions, this literature rested largely on case reports (where positive associations are much more likely to be published). It became clear that, apart from epilepsy, the strongest association of autism with medical conditions related to two strong genetic conditions—fragile X and tuberous sclerosis (39).

It has become increasingly clear that genetic influences are complex but important in the pathogenesis of autism. One interesting development has been the recognition that the "broader spectrum" of social vulnerability (NOT qualifying for an ASD diagnosis as such) may reflect the operation of some of these factors. There clearly is the potential impact of some environmental factor or factors in this complex process (40), although to date it is the genetic factors that appear to be most robustly elucidated. Many genes potentially involved have now been identified and these

often appear to have an important role in the central nervous system. In perhaps 10% of cases, some associated genetic syndrome associated with autism can be identified, that is, in the majority of cases this is not the case. An interesting related issue is the frequent association of autism with other conditions, for example, anxiety problems, attention difficulties, that themselves may have strong genetic components.

FIGURE 5.2.1.1. Differences in eye tracking in an individual with high functioning autism (*bottom line*) and a typically developing person (*top line*) watching an intensely social scene; the individual with autism focuses on the mouth losing much of the social-affective information conveyed in the top part of the face.

Social Features

Kanner emphasized the centrality of "autism" as one of the two defining features of the condition in his initial description of the syndrome; subsequent research has consistently shown him to be correct, in that the social difficulties observed appear to be a (if not the) hallmark of the condition (41,42). The social problems are not simply due to cognitive disability, and if anything they probably lead to the latter (43). Social difficulties can be most profound in the youngest individuals but, over time, may progress to the point where the child passively accepts interaction or develops a one-sided and eccentric interactive style (44). Social and adaptive skills are among the more powerful predictors of ultimate outcome (45). Even for individuals with "optimal outcome," some social eccentricity may remain (46).

Communicative Features

In the past a majority of individuals were mute or had very limited communicative speech but with earlier and more intensive intervention, this appears to be changing (47). It is, however, common for parents to become concerned because of the delayed development of speech (48). Communicative difficulties are a central aspect of the condition. For the individual who does talk, speech is often remarkable in various respects. The child may repeat sentences or phrases (echolalia) either one just heard or remembers from the past; this may be functional in some sense and also reflects the unusual "gestalt" learning style typical of ASD. Problems with pronoun use are frequent (49). Deficits in the development of expressive language are one of the more frequent sources of initial concern for parents of children later diagnosed with autism. Often prosody is unusual (monotonic or poorly inflected with a loud voice volume) and idiosyncratic language may be observed (and is often only understood by parents or family members). Even for the most able individual, problems with pragmatic language are frequent, for example, in understanding figurative language, humor, sarcasm, irony, and so forth (49).

Behavioral Features

In addition to emphasizing social problems, Kanner also emphasized the presence of unusual difficulties with change—"insistence on sameness"—in the cases he described. Often the contrast between a child's lack of social interest stands in stark contrast to his sensitivity to environmental change or interest in aspects of the nonsocial world, for example, early interest in fans, letters, iconic images. Occasionally the child is attached to an unusual object (differing from transitional objects, in that this is usually hard rather than soft and the category of object is more important than the specific object). Although parents are sometimes worried that children may be deaf, the child may actually respond with great alarm to some sounds. Younger children often are more interested in the taste, texture, and smell of objects than their function. Unusual sensory interests often antedate the development of more "classic" stereotyped mannerisms.

Cognitive Functioning

It took investigators and clinicians many years to realize that autism/ASD could be, and at that point usually was, associated with intellectual deficiency. The child's ability to cooperate with some parts of IQ tests (e.g., puzzles) was in stark contrast to the child's verbal ability but these deficits were "written off" as due to poor testability or negativism. It gradually became clear that unusual cognitive profiles are common in individuals with social learning problems and are powerful predictors of

outcome. Scatter on cognitive testing is common often in children with more classic autism exhibiting better nonverbal than verbal abilities. The reverse profile may be seen in individuals with Asperger disorder (11).

In a minority of cases, individuals may exhibit remarkable abilities, for example, in drawing, calculating dates, or memory. These "savant skills" sometimes stand in stark contrast to the individual's overall ability and may offer insight into unusual approaches to solving problems (50). Sometimes these skills diminish with age, although not always. Typically one skill is exhibited. Similarly in Asperger's, intense special interests are usual and often interfere with the individual's learning and family functioning although, on occasion, these can be turned into potentially valuable vocational skills (51); unfortunately, they can sometimes lead to legal issues (52).

ONSET

Kanner initially thought that autism was congenital and while this seems often to be true, it is the case that in a small number of cases (perhaps 1 in 5) parents will report a loss of skills. In the majority of cases, warning signs of autism are evidence in the first year of life (see Table 5.2.1.5) and these warning signs are used in screening for the condition (53). Early concerns may have to do with the concern that the child is deaf or that speech is delayed; sometimes, unusual interests or preoccupations may be resorted.

The issue of "regressive" autism is a complex one. Sometimes parents report regression but also report earlier delayed milestones or sometimes it is less a regression than a failure to progress (54). However, in a small number of cases there is a clear, marked, and dramatic regression with loss of words, deterioration of social skills, and loss of adaptive skills. DSM-IV and ICD-10 included the concept of childhood disintegrative disorder to accent for these cases which, unfortunately, appear to have a much worse prognosis (55).

PHYSICAL CHARACTERISTICS, PATHOLOGY, AND LABORATORY EXAMINATION

Kanner's initial report noted the absence of obvious physical dysmorphology. Subsequently, autism has been noted to be associated with several genetic conditions —notably, fragile X and tuberous sclerosis; and physical signs may be associated with the condition in these cases (39). As noted previously, the risk for onset of epilepsy is markedly increased with peaks on onset early in life and again in adolescence (39). In some cases macrocephaly develops in toddlerhood (56). A small number of neuropathologic studies have been conducted that suggest issues in the organization of the cortex (57). As noted previously, a considerable body of work

on brain mechanisms has now emerged from studies using EEG and functional magnetic resonance imaging (fMRI). Laboratory studies are guided by history and physical examination; the American College of Medical Genetics and Genomics periodically updates its recommendations for genetic studies (58).

DIFFERENTIAL DIAGNOSIS AND ASSESSMENT

Autism must be differentiated from intellectual deficiency, communication disorders, severe deprivation, and sensory impairment (particularly deafness). In intellectual deficiency without autism, social skills are usually on par with cognitive development. In the communication disorders (apart from the new "SCD"), social skills are generally well preserved, even in the face of major language vulnerabilities. For individuals with Asperger disorder, the differential diagnosis may include personality problems and occasionally psychotic disorders are considered—the intense circumscribed interests and marked social impairments are usually indicative of Asperger's but in some cases differentiation can be difficult (11).

TABLE 5.2.1.5

SYMPTOMS OF AUTISM IN THE FIRST 3 YEARS OF LIFE

	0–12 Months	12–36 Months
Social	Limited ability to anticipate being picked up Low frequency of looking at people Limited interest in interactional games Limited affection toward familiar people Content to be left alone Limited range of facial expression	Abnormal eye contact Limited social referencing Limited interest in other children Limited social smile Low frequency of looking at people Limited sharing of affect/enjoyment
Play	Little interest in interactive games	Limited functional play No pretend play Limited motor imitation
Communication	Poor response to name (does not respond to call) Does not frequently look at objects held by others	Low frequency of verbal or nonverbal communication Failure to share interests (e.g., through pointing, sharing, giving, showing) Poor response to name Failure to respond to communicative gestures (pointing, giving, showing) Use of others' body as a tool (pulls hand to desired object without making eye contact, as if *hand* rather than person obtains object)

Restricted interests/behaviors	Mouths objects excessively Does not like to be touched	Unusual sensory behaviors Hyper/hyposensitivity to sounds, texture, tastes, visual stimuli Hand or finger mannerisms Inappropriate use of objects Repetitive interest/play

Reprinted with permission from Volkmar F, Chawarska K, Klin A: Autism in infancy and early childhood. *Annu Rev Psychol* 56:315–336, 2005.

It is typical for individuals with autism to have problems in multiple areas of functioning, with areas of strength and weakness. It is important to understand these profiles as they may indicate approaches to treatment (using strengths to address weaknesses) (11). It is also important to keep in mind the broad range of syndrome expression. It is usual for intellectual testing to reveal significant scatter with social and language-based skills, lower than would be expected, given the child's nonverbal abilities (the opposite profile may be seen in Asperger's). It is often the case that various specialists are involved, for example, psychologists, speech pathologists, special and regular education teachers, occupational and physical therapists. A wide range of normative assessment instruments can be used to assess intellectual level, communicative skills, academic achievement, and other domains (59); given the unusual and often rigid patterns of learning in ASD assessment should address the issue of adaptive skills—that is, the child's capacity to generalize skills to "real-world" settings (59).

A number of screening instruments for preschool and school-age children (53), as well as diagnostic instruments (60), have been developed. Of the former, probably the most widely used is the M-Char (61). A number of good diagnostic instruments have been developed and include the Autism Diagnostic Interview-Revised (an interview for parents) (62) as well as the Autism Diagnostic Observation Schedule (ADOS) (63) (both instruments require relatively extensive training). The Childhood Autism Rating Scale—second edition (64) is frequently used in schools. It is important to realize that the diagnostic instruments presently available have, for the most part, focused on school-age children with borderline to mild intellectual disability, that is, their use may be more complex in older or younger or lower or higher cognitively functioning individuals.

Initial examination should include a physical and careful history with referral to neurology or genetics as indicated for additional assessment. Hearing and vision should be evaluated. As part of the examination of the child observation in both structured and unstructured settings is helpful. A number of rating scales and diagnostic instruments have been developed (60); these can be based on parent report and/or child assessment. It is important to keep in mind that the traditional rating scales and checklists often work best in children of school age with borderline to mild intellectual disability, that is, older individuals and the very young may present diagnostic challenges as do the more intellectually gifted and more intellectually

impaired. Assessment procedures are summarized in Table 5.2.1.6.

The strongest associations of autism are with a handful of medical conditions. Probably the strongest connection is with epilepsy that develops in about 20% of cases of individuals with strictly diagnosed autism. Autism is also observed at higher than expected rates in connection with two strongly genetic conditions—fragile X syndrome and tuberous sclerosis. Brain size appears to be increased in toddlers with autism, although this difference becomes less pronounced over time. Medical assessment should include a careful medical and family history. Testing for fragile X and of hearing is typically indicated. More extensive genetic testing is indicated by physical examination or family history. Signs of possible seizures should prompt EEG and neurologic examination. Neuroimaging studies may be indicated by examination or history.

COURSE AND PROGNOSIS

As noted previously, parents are typically worried about their child's development in the first year of life—typical concerns centering on language delay or possible deafness. However, the first screening instruments (at present) only begin to be useful around 18 months so that delay in diagnosis is relatively common. In addition, some children seem to develop normally for a time and then lose skills. Sometimes children at ages 1 or 2 will exhibit the more typical social communication problems but not yet all the unusual behaviors (although sometimes exhibiting precursors to these behaviors, for example, staring at fans or fixating on some object more than on parents and family members). However, by age 3 the vast majority of children with ASD will exhibit the diagnosis (65) and often intervention has started even before that time due to language delay (66). Early diagnosis is increasingly common and schools are mandated to provide services after the age of 3.

TABLE 5.2.1.6

EVALUATION PROCEDURES: AUTISM AND PERVASIVE DEVELOPMENTAL DISORDERS

1. Historical information
   - Early development and characteristics of development
   - Age and nature of onset
   - Medical and family history
2. Developmental and psychological assessment
   - Intellectual level and profile of learning
   - Communicative assessment (receptive and expressive language skills, use of nonverbal communication, pragmatic use of language)
   - Adaptive behavior (ability to generalize skills to real-world settings)
   - Occupational/physical therapy assessments as appropriate
3. Psychiatric examination
   - Nature of social relatedness (eye contact, attachment behaviors, reciprocity, insight)
   - Behavioral features (stereotypy/self-stimulation, resistance to change, unusual sensitivities to the environment)
   - Language/communication difficulties (echolalia, presence of communicative speech, etc.)

Play skills (nonfunctional use of play materials, symbolic play, and imagination)

4. Medical evaluations

Search for associated medical conditions, genetic abnormalities, presence of seizures

With additional tests as needed

Hearing/vision test

Additional consultation (neurologic/pediatric/genetic) as indicated by history and current presentation (see reference 58 for current genetic testing recommendations)

Examination (e.g., EEG, CT/MRI scan, chromosome analysis)

Reprinted with permission from Volkmar FR, Lord C, Bailey A, Schultz RT, Klin A: Autism and pervasive developmental disorders. In: Martin A, Volkmar FR, Lewis M (eds): *Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook*. 4th ed. Philadelphia, PA, Wolters Kluwer, 391, 2007.

Young children with autism may exhibit an aloof social style, although sometimes the more cognitively able are more passively accepting of social interaction or somewhat one sided and eccentric as they mature (44). Behavioral difficulties often increase during childhood and may further increase in adolescence before diminishing in young adulthood. Although the DSM-5 definition of ASD is somewhat restricting in the broader sense of the autistic spectrum, it is very clear that a tremendous range of features and symptoms are exhibited. See Box 5.2.1.1 for an illustrative case.

Over time, the prognosis of autism appears to have improved substantially. In the 1980s, about 90% of children with classic autism were functioning in the intellectually impaired range. At that time, only perhaps 50% of individuals with autism would ever speak. Perhaps two-thirds of cases were institutionalized as adults with only a small fraction living independently. As time has gone on, there appear to have been major changes in outcome, for example, perhaps only 20% or so now remain mute, many individuals are now functioning in the normal cognitive range and often are going to college, perhaps 30% or so (at least) are independent and self-sufficient as adults (67). Indeed some individuals become sufficiently capable that they “lose” their diagnosis (although often retaining some social vulnerability) (46). The change in outcome reflects several factors including, to some extent, changes in diagnostic practice but probably more importantly, providing of early and more effective intervention.

BOX 5.2.1.1

CASE REPORT—AUTISTIC DISORDER

John was the second of two children born to middle-class parents after normal pregnancy, labor, and delivery. As an infant, John appeared undemanding and relatively placid; motor development proceeded appropriately, but language development was delayed. Although his parents indicated that they were first concerned about his development when he was 18 months of age and still not speaking, in retrospect they noted that, in comparison to their previous child, he had seemed relatively uninterested in social interaction and the social games of infancy. Stranger anxiety had never really developed, and John did not exhibit differential attachment behaviors toward his parents. Their pediatrician initially reassured John's parents that he was a “late talker,” but they continued to be concerned. Although John seemed to respond to some unusual sounds, the pediatrician obtained a

hearing test when John was 24 months old. Levels of hearing appeared adequate for development of speech, and John was referred for developmental evaluation. At 24 months, motor skills were age appropriate and John exhibited some nonverbal problem-solving skills close to age level. His language and social development, however, were severely delayed, and he was noted to be resistant to changes in routine and unusually sensitive to aspects of the inanimate environment. His play skills were quite limited and he used play materials in unusual and idiosyncratic ways. His older sister had a history of some learning difficulties, but the family history was otherwise negative. A comprehensive medical evaluation revealed a normal EEG and CT scan; genetic screening and chromosome analysis were normal as well.

John was enrolled in a special education program, where he gradually began to speak. His speech was characterized by echolalia, extreme literalness, a monotonic voice quality, and pronoun reversal. He rarely used language in interaction and remained quite isolated. By school age, John had developed some evidence of differential attachments to family members; he also had developed a number of self-stimulatory behaviors and engaged in occasional periods of head banging. Extreme sensitivity to change continued. Intelligence testing revealed marked scatter, with a full-scale IQ in the moderately retarded range. As an adolescent, John's behavioral functioning deteriorated, and he developed a seizure disorder. Now an adult, he lives in a group home and attends a sheltered workshop. He has a rather passive interactional style but exhibits occasional outbursts of aggression and self-abuse.

Comment: With earlier intervention, more children with autism are doing better. Unfortunately in this case, although the child developed speech, his overall outcome has not been as good as might have been hoped.

Adapted from Volkmar FR, Lord C, Klin A, Cook E: Autism and the pervasive developmental disorders. In: Lewis M (ed): *Lewis's Child and Adolescent Psychiatry: A Comprehensive Textbook*. Philadelphia, PA, Lippincott, 595, 2002.

Associated clinical problems include the increased risk for epilepsy (often of adolescent onset) as well as several psychiatric problems. These include attention problems in middle childhood and, particularly in the more cognitively able, anxiety and depression in adolescence and young adulthood. There may be an increased risk for other problems as well. Unfortunately, information on aging in autism is severely limited with most outcome studies stopping in early adulthood (68).

TREATMENTS

After autism was first identified, the only available treatments were psychotherapy—which had little impact. During the 1960s, the first school for children with autism was founded and during the 1970s, the first studies appeared suggesting that structured educational interventions were more effective than psychopathy (69). The passage of public law 94-142 mandated schools to provide educational service for all children and this mandate increased services and research. Over time, more treatments have been extensively researched so that many individual intervention procedures as well as some model programs and drug treatments can now be regarded as having some, or extensive, basis in evidence (70). Areas of intervention typically address the core diagnostic features of autism—deficits with social interaction and communication—but also include other issues including problems in

learning (47). As a result of the growing body of work on assessment and intervention, practice guidelines have also now appeared (71,72).

Educational and Behavioral Treatments

Beginning in the 1970s, a number of research-based methods have been used to enhance effective learning. Behavioral techniques were among the first to be developed based on principles of learning derived from psychology and principles of learning theory. These techniques have a strong research basis (73) and have been used in a range of settings and for a range of problems. These also have been integrated into model treatment programs and serve as the basis for programs using applied behavior analysis (ABA) (73). Social skills are another area for support and a range of methods have been used to teach social skills (74)—ranging from use of peers to teach preschoolers, to social skills groups in children and adolescents. Peer-based approaches have, by far, the strongest base in the research literature and tend to revolve around integration of preschoolers and young school-age children in mainstream educational settings (75). Similarly, various approaches can be used to foster communication (in the broader sense) as well as spoken language (49). For children who don't speak, augmentative approaches (76) can be used to increase functional communicative abilities. For the more cognitively able and verbal individuals, work may center on social language use. Finally, it is important to note that organizational issues can be significantly helped with supportive technology—methods range from low-to-high tech. These can include simple things like visual schedule, timers, and so forth to organizational software and apps designed specifically to help individuals with ASD (77).

In addition to evidence-based intervention techniques several evidence-based model treatment programs have been developed. These share many similarities and some differences (70). Model programs for intervention fall into four general types. Probably the most widely known are behaviorally based/focused programs or ABA programs which employ principles from behavioral psychology to teach and can be very effective for younger and more impaired individuals; discrete trial teaching is one of the more frequently used methods in these programs (78). In contrast, more developmentally oriented programs (79) build on the child's interest using developmentally oriented and focused intervention. Pivotal response training (PRT) is a third approach that uses behavioral techniques within a more developmentally oriented framework (80). Eclectic approaches exist, such as a program used statewide in North Carolina (81). Autism-oriented curricula have also been developed, and many techniques and methods from model programs and empirically validated interventions are employed within public school settings (82). It is important to emphasize that in the United States, children with ASD are entitled to school programs beginning at age 3 years (and preschool services before that); this

likely has contributed to the improved outcome that is now more frequently seen.

Pharmacologic Treatments

At present no specific drug treatments exist for the core social disability of autism (although efforts are underway to examine potential treatments). Effective drug treatments are available to help with the “irritability” often seen in inidividuals with ASD. In addition, a host of medications (and some behavioral techniques) can be used to treat attention difficulties, anxiety, and depression (83). It is important to be judicious in the use of drug treatments and avoid overmedication. It is important as well to keep in mind the special issues posed in each case, for example, abrupt behavioral deterioration associated with face slapping or head banging in a more cognitively impaired individual should prompt a search for any associated ear infection, erupting wisdom teeth, etc. (39). Similarly, it is important to realize that a bad educational program cannot be medicated. The clinician should be alert to any features that are unusual, for example, learning that a behavioral problem occurs only in one situation or context should prompt careful review. Finally, it is important to note that having behavioral data can greatly help monitor medication effects (as long as only the medication is being adjusted). Despite extensive research over the last two decades, there are no drug treatments that are broadly considered to be effective for the core symptoms of ASD. A large number of drugs have been studied in ASD, none to a greater extent than the digestive hormone secretin, which has consistently been found to be ineffective (84–86). Other agents have been successful in treating behavioral symptoms of ASD and associated psychiatric comorbidity. The drug risperidone has also been demonstrated to reduce symptoms of repetitive behaviors, but without impact on social deficits (87). Drug treatment is not routinely indicated in all individuals with ASD and should be considered only to target problematic symptoms. In this section we consider the evidence base for the use of medications to manage behavioral symptoms of ASD. In addition, we will explore treatments for comorbid symptom dimensions. For the purpose of this section, we will leave aside the issue of distinguishing between a true comorbidity and a set of symptoms that is in fact part of an underlying ASD. Rather we will employ a pragmatic lens toward understanding how the literature can inform the use of medication in individuals who may experience a range of symptoms in the context of an ASD diagnosis.

It is not standard care to use medication in all individuals with ASD. There is insufficient evidence to support the use of medication for core ASD symptoms. By contrast, early behavioral and educational interventions are safe and effective, and these should be emphasized in treatment planning.

Medication may be particularly useful for managing irritability and aggressive behavior, and in this regard, risperidone and aripiprazole are significantly superior to other agents in terms of the extent of their evidence base. Both are however

associated with significant adverse metabolic effects, potentially limiting their use and necessitating careful monitoring. Similarly, pharmacotherapy for either inattention or repetitive behaviors is inconsistently helpful and with greater potential for adverse effects, and in each case a decision to initiate drug treatment should involve a thoughtful discussion with a patient and their family, setting appropriate expectations and highlighting relevant risks. A number of medications are prescribed in ASD which have not been subjected to rigorous study, despite evidence that medication tolerance and response rates may differ substantially in these individuals. This highlights both the need for a cautious clinical approach and ongoing research. As noted previously, a growing body of evidence-based treatments are available and it is incumbent on the practitioner to review this small but growing body of evidence (83,88).

AGGRESSION AND IRRITABILITY

Aggression is a problematic behavior with consequences for the individual and the family system. Aggressive behavior is more common in individuals with ASD (89), and an important predictor for engagement with crisis management services and medication utilization (90). A number of atypical antipsychotic medications have been studied for this intervention, including several randomized controlled trials.

Risperidone

Risperidone was the first antipsychotic medication shown to be effective for serious problem behaviors in ASD, including aggression, tantrums, and self-injurious behavior (91). In addition to behavioral improvements, measures of irritability were also substantially improved. Improvements were noted in around two-thirds of participants. These findings have since been replicated (92). In both these studies the dose was lower than typically used for the treatment of psychosis. However, in both studies, risperidone was associated with around 4 lb greater weight gain than placebo over an 8-week period. The potential benefits may not always outweigh the significant morbidity resulting from this degree of weight gain, and the choice to use this medication should include a clear discussion with the patient and family about this and other adverse effects.

Aripiprazole

More recent study supports the use of aripiprazole as a similarly effect agent for irritability and associated behaviors (93,94). The degree of weight gain appears to be less than for risperidone, but remains a significant adverse effect. Extrapyramidal symptoms, sedation and presyncope, were also reported as potentially significant

side effects. Longer-term open-label study suggests that weight gain on aripiprazole may eventually plateau, but may be associated with metabolic abnormalities in a significant subset of patients (95).

Haloperidol

The earliest evidence from randomized controlled trials for behavioral symptoms of ASD supported the use of haloperidol (96). Although effective for a number of maladaptive symptoms, including stereotypies, labile and angry affect, its use was associated with significant side effects of sedation, and a 25% incidence of acute dystonia. Concern regarding the latter side effect is likely the primary reason why haloperidol is less often used for ongoing treatment of aggression in ASD. There is little recent study of haloperidol for this indication, despite concerns related to the metabolic side effects of newer agents.

Other Antipsychotics

There is very limited robust evidence supporting the use of other antipsychotics in ASD. One small randomized controlled trial of olanzapine did not demonstrate improvement on measures of irritability (97), and an open-label study of quetiapine found no clear evidence of benefit, with significant adverse effects (98). In clinical practice, it appears common for patients with ASD to be prescribed a broader range of antipsychotics. This is not an evidence-based approach. It should be noted that not all patients with ASD will respond to medication, or may experience only a partial improvement. This should serve as an impetus to explore potential exacerbating or sustaining factors for these symptoms and to explore additional behavioral treatments and does not justify the use of unproven treatments with significant potential for side effects.

Antiepileptic Drugs

Sodium valproate has been found to be an effective treatment for aggression in ASD in one randomized controlled trial (99). The effect size reported in this study was moderate. Side effects including weight gain were uncommon. Additional study could support the use of valproate as a more tolerable treatment option. Of the other antiepileptics, levetiracetam and lamotrigine have been studied in a randomized fashion and found to be ineffective (100,101). Owing to the high comorbidity between ASD and epilepsy, a broader range of antiepileptics have been used in ASD —however, this does not support their utility for managing behavioral symptoms, and they should not be considered a first line for this indication.

REPETITIVE BEHAVIOR

Selective Serotonin Reuptake Inhibitors (SSRIs)

Repetitive behavior, including self-injury, is a treatment-refractory symptom. An early trial was promising in reporting a moderate to large effect size for the use of fluoxetine in reducing repetitive behaviors in ASD (102). However, a subsequent study using citalopram was negative (103), and a recent Cochrane review found no evidence supporting the use of SSRIs in children with ASD (104).

Atypical Antipsychotics

Studies of risperidone and aripiprazole, in addition to detecting improvements in irritability and aggression, also found improvement in the symptom dimension of repetitive behavior. However, these effects were quantified using the Aberrant Behavior Checklist stereotypy subscale, whereas most of the SSRIs made use of the Children's Yale-Brown Obsessive Compulsive Scale. The aberrant behavior checklist stereotypy (ABC-S) captures a broad range of movements which may include purposeful behaviors (such as waving or shaking extremities) that may improve in the context of decreased irritability or anxiety—these behaviors are phenomenologically distinct from the more distinct subtype of stereotyped behavior which is considered a core dimension of ASD (105). It is therefore unclear whether atypical antipsychotics truly alter a core symptom dimension of ASD, or whether this apparent effect is attributable to improvements in irritability that are being captured by the instruments used in these studies.

Other Agents

A number of studies have examined the utility of tricyclic antidepressants; clomipramine in particular has demonstrated efficacy in a randomized controlled trial (106). In practice, its use is limited by concerns regarding side effects, including severe urinary retention and worsening aggression (107).

INATTENTION AND ATTENTION DEFICIT HYPERACTIVITY DISORDER (ADHD)

Stimulants

Comorbid difficulties with attention are common in ASD and there is much argument about whether or not this represents a true comorbid diagnosis or an expected

symptom dimension in ASD. The answer to this question is less relevant in the context of evidence that supports the use of stimulants in individuals with ASD who have significant ADHD symptom. A randomized controlled trial of methylphenidate in children ($N = 72$) with ASD and ADHD symptoms found a response rate of 49% (108). This is lower than rates reported for children with ADHD who do not have ASD. In addition, effect sizes reported were smaller, and side effects were more frequent. Given these findings, stimulant treatment remains appropriate in some cases, but the threshold may be higher given the greater potential for adverse effects and lower likelihood for a positive outcome.

Other Agents

In clinical practice, the alpha-2 agonists guanfacine and clonidine are frequently used for both ADHD symptoms and irritability in children with ASD. Their efficacy is well established in larger trials of children without ASD, and there is a small body of evidence specific to ADHD symptoms in ASD (109). A trial of atomoxetine reported moderate improvement in ADHD in children with ASD compared to placebo, with adverse effects comparable to studies in non-ASD populations (110).

Social Deficits

There are no medications which have consistently been shown to be effective for the social deficits which characterize ASD. The neurohormone oxytocin remains a focus of study, with recent meta-analysis suggesting that current data are potentially promising, but that additional, rigorous research is required (111). A subsequent clinical trial reported that oxytocin enhanced orientation to social information in specific subgroups of individuals with ASD only (112).

A recent study of the glutamatergic agent memantine showed good tolerance but no statistically significant improvement in core ASD symptoms, including social domains.

ALTERNATIVE TREATMENTS

Nonestablished (i.e., alternative and complementary) treatments are frequently used by parents. These include a range of interventions from special diets or megavitamins to correction-presumed nutritional problems, chelation to rid the body of presumed toxic meals, to somatic treatments. By definition, evidence is either lacking or, less commonly, multiple negative studies are taken to strongly suggest the treatment doesn't work (the use of secretin and facilitated communication are examples of this). Complementary treatments are used along with evidence-based treatments and alterative treatment instead of such treatments. Probably between 50% and 75% of

families will use such treatment at some point (113).

As a practical matter, it is important to elicit information from parents about all treatments they are using and engage in a supportive and understanding way with them regarding complementary interventions. When negative evidence is available it can be pointed out, and when treatments carry some risk (e.g., chelation) this should also be discussed. The risk of alternative treatments displacing evidenced-based interventions should also be highlighted. Helping parents secure quality sources of information is important.

SUMMARY AND DIRECTIONS FOR FUTURE RESEARCH

Over the past decades, considerable progress has been made: we now understand that autism is a strongly brain-based disorder, is also strongly genetic, and that it responds best to structured treatment approaches. A major focus of research has been on understanding the social brain processes involved in autism and it is clear that there are fundamental differences in such processes such as face processing, monitoring ongoing social interaction, perception of biologic movement, and so forth. Although a number of findings have proved robust, others have not. One complexity is the tendency for investigators to employ slight variations in replication studies, for example, differences in sample, methods, materials, techniques, can lead to differences in results which must, in turn be sorted out. With this caveat, it is exciting that genetic research and work on brain mechanisms is starting to converge.

Findings from more recent large scale genetics research are informing new approaches to development of pharmacotherapy—such as the targeting of glutamate receptors and, perhaps, processes more fundamentally connected with social cognition and learning.

Translation of promising preclinical research into positive results in human studies remains a prominent challenge. Oxytocin treatment continues to offer promise, although recent mixed results highlight the need for further study (114). Currently available agents warrant further study for behavioral symptoms—in particular, newer atypical antipsychotics like ziprasidone offer a promise of improved side-effect burden and appear to be effective in clinical practice. Nicotinic agents appear to be a promising area for further investigation, with some early reports of positive effects for both cognition and behavioral symptoms (115).

CHAPTER 5.2.2 ■ INTELLECTUAL DISABILITY

FRED R. VOLKMAR, ELISABETH M. DYKENS, AND ROBERT M. HODAPP

DEFINITION

Traditionally intellectual disability (ID) (previously termed mental retardation) has been defined based on three key features: subnormal intellectual functioning, commensurate deficits in adaptive functioning, and onset before 18 years. Of these three criteria, the first two are most often discussed. Subnormal intellectual functioning is characterized by an intelligence quotient (IQ) lower than 70, based in most cases on the administration of an appropriate standardized assessment of intelligence. Deficits in adaptive skills, which involve one's social and personal sufficiency and independence, are generally measured on instruments such as the recently rerevised Vineland Adaptive Behavior Scales (1). Various levels of ID were specified in the DSM-IV and ICD-10: mild (IQ 50 to 70), moderate (IQ 35 to 49), severe (IQ 20 to 34), and profound (IQ <20). The overall diagnostic approach to ID in DSM-IV and ICD-10 is summarized in Table 5.2.2.1.

The DSM-5 (2) approach is largely consistent with this approach albeit with a few changes. Most importantly the name of the condition has been changed to ID. Cognitive intellectual functioning should be two or more standard deviations below the mean (with some potential for flexibility in the "borderline" range). In addition to the name change the condition is now grouped as one of the neurodevelopmental disorders (these include ASD, communication disorders, and so forth); this was part of a broader effort to avoid having a childhood disorders section of the manual. ID is defined based on three features: deficits in intellectual functioning (as defined by both clinical observation and standardized assessments of intelligence), deficits in adaptive functioning (the capacity to cope with real world situations—again assessed both clinically and by standard tests), and onset in the developmental period. Specifiers can be used to note severity, associations with specific medical problems, and so forth. Accordingly this generally is in consistent with the approach in DSM-IV and ICD-10. It is important to note that the validity of specifiers (e.g., severe vs. profound levels) remains the topic of debate, the precise age of the "developmental period" is left unclear, and, rather oddly, it is suggested that deficits in adaptive function must be "directly related" to the cognitive deficits. On the latter score this might be complicated in the case of an individual with ASD and ID since the ASD may be an even greater factor impacting delayed adaptive skills. Other issues (see Chapter 4.7) arise with the overarching DSM-5 move away from multiaxial classification which was particularly important in noting comorbid conditions associated with ID.

TABLE 5.2.2.1

OVERALL DIAGNOSTIC APPROACH TO INTELLECTUAL DISABILITY IN ICD-10 AND DSM-IV

1. Cognitive ability (as assessed by an appropriate standardized test) in the significantly subaverage range (IQ below 70)
2. Adaptive skills (also as assessed by an appropriate standardized test) also below 70
3. Onset in the developmental period

   Levels of intellectual deficiency

   - Mild (IQ 50–69) (ultimate adult cognitive level or mental age 9–12 yrs)
   - Moderate (IQ 35–49) (ultimate adult cognitive level or mental age 6–9 yrs)
   - Severe (IQ 20–34) (ultimate adult cognitive level or mental age 3–6 yrs)
   - Profound (IQ <20) (ultimate adult cognitive level or mental age <3-yr level)

   Note: Clinical sensitivity is needed, especially in situations where cultural, language, or others issues complicate usual assessment.

Most persons with ID in childhood are those with mild ID (about 85% of cases); the remainder of cases are comprised of those with moderate (about 10%), severe (about 4%), and profound (1% to 2%) ID (Fig. 5.2.2.1). In the past, the distinction was made between educable (IQ 50 to 70) and trainable (IQ <50). Although no longer commonly used, this distinction is important. Persons with mild ID often have psychiatric difficulties that are fundamentally similar (if generally more frequent) to those seen in the general population; this is not true for more severely impaired persons. Similarly, specific medical conditions associated with ID are more likely in the group with an IQ lower than 50, whereas poverty and lower socioeconomic status are more frequent in the group with mild ID (3). The proportion of persons with severe and profound ID is higher than would be expected given the normal curve, reflecting the impact of genetic disorders and severe medical problems on development (4).

The tests chosen for assessment of intellectual functioning should be appropriate to the patient, have reasonable reliability and validity, and be administered in a standardized way by appropriately trained examiners (see Chapter 4.4, for a discussion of psychological assessment). Unfortunately, in some situations, the selection of an appropriate test can be difficult, such as for a very low functioning person. Other aspects of assessment can also be problematic, such as when some modification must be made in terms of administration given the specific circumstance. Such modifications may limit the validity of the results obtained. The examiner must then make an informed decision depending on the nature of the issue at hand, for example, determination of eligibility for services versus information on levels of functioning that can guide remediation. Particularly in terms of eligibility for services, it is critical that the examiner administer the test in exactly the standardized fashion. Measures of adaptive skills are generally based on parent or caregiver report, although, in some cases, the person may be interviewed directly. In essence, the conceptual notion is that the term *adaptive skills* refer to the performance of day-to-day activities required for personal or social self-sufficiency.

Percent of Cases

Mild

Profound

Severe

Moderate
FIGURE 5.2.2.1. Levels of intellectual disability.

The inclusion of adaptive skills in the definition of ID rests on the observation that some persons with IQ scores below 70 may, as adolescents or adults, have learned sufficient adaptive skills, so that they are able to function totally or largely independently. Technically, then, such individuals would not meet criteria for ID. This situation is more typical of persons who, as children, score in the mildly retarded range (5).

The approach to the definition of ID is fundamentally the same in the 10th edition of the *International Classification of Diseases* (ICD-10) (6). However, the definition of ID promulgated by the American Association of Mental Retardation (AAMR)—first in its 1992 manual (7) and later (in revised form) in its 2002 manual (8)—discards the use of IQ levels in favor of a “needs-based” nosology that identifies the intensity of supports that persons require to function best within multiple adaptive domains. This definition also gives the clinician leeway to extend the upper IQ bound to 75; this seemingly small increase would actually considerably broaden the diagnostic concept of ID, potentially doubling the total number of cases (9). The AAID definition was much criticized and has had very little empirical support. Partly as a result, the AAID definition (particularly its 1992 version) has not been widely used either in research (10) or in state guidelines (11).

HISTORICAL NOTE

Interest in ID can be traced to antiquity (12,13). Modern interest in ID began at the time of the enlightenment and increased greatly during the 19th century; this emphasis

occurred at the time of great social upheaval and as infant and child mortality began to decline. There was increased interest in children, in education, and in the role of experience (nurture) versus endowment (nature). The interest in the "nature–nurture problem" is exemplified in Itard's work with Victor, a child who was thought to be wild or "feral" but who may have had autism (14,15).

Subsequently, educators such as Seguin began to develop specific educational methods for stimulating children's development. By the latter half of the 19th century, many facilities had been developed for the care of persons with ID. Although the initial goal of such facilities was to provide a period of treatment before the child was returned to the family, these institutions gradually became places for custodial care (12). This problem has led to a strong counterreaction in recent years and to a renewed emphasis of caring for persons with ID in their homes and communities (16).

During the 19th century attempts were made to distinguish between levels of ID by using what now would be seen as rather pejorative terms (imbecile, cretin, idiot). Originally, the etiologic basis of any such distinctions was quite limited. On one hand, there was little systematic information on intellectual functioning that could be used for purposes of categorization. On the other, there were few known etiologic causes of ID.

Toward the end of the 19th and the beginning of the 20th centuries, both these limitations began to be addressed. Binet developed the first test of intelligence, which was translated into English and adapted in the United States by Terman (17,18). As a model psychometric assessment instrument for many years, the Stanford–Binet test allowed much more precise characterization of levels of ID. In addition, Terman had the brilliant notion of taking the mental age, dividing it by the child's chronologic age, and multiplying this quotient by 100. The resulting IQ score allowed for comparisons across children of different ages. Although Binet had originally developed his scale to identify children who were delayed in order to help them, the IQ score quickly became the object of much study.

Faith in the IQ as a predictor variable led to several unfortunate practices. First, developmental testing began to be performed on infants and young children (19). Second, proponents of the new tests believed that, when the test was properly administered, the resulting score from an IQ test was fixed and reflected a person's genetic endowment. This proved incorrect. In a classic study, Skeels and Dye (20) demonstrated this practically by transferring infants and young children from an orphanage to a home for the "feeble minded" to make the children normal. This fantastic plan had been prompted by clinical observation that children in the home for the feeble minded received considerably more stimulation than those in the orphanage. Skeels (21) later reported major differences in outcomes for these better-cared-for children, both in childhood and in later adult life. By the 1940s and 1950s, there was increased awareness that the IQ score was indeed the product of both

experience and endowment, and therapeutic optimism again increased for improving the functioning of children with ID.

In addition to the focus on intellectual functioning, it also became apparent that the person's capacity to engage in appropriate self-care or "adaptive" skills was a major aspect of ID. In the 1930s, the psychologist Edgar Doll developed the Vineland Social Maturity Scale in an attempt to quantify such skills. Originally revised two decades ago (22), the Vineland Adaptive Behavior Scales have recently been rerevised (1). The Vineland Scales, now published in several versions, continue to serve as an important tool in the assessment of children with ID. Along with lower IQs, deficits in adaptive skills are now required as part of the diagnosis of ID. In contrast to IQ, however, adaptive skills can be readily taught.

Another major line of work centers on the origin of ID syndromes. In the 19th century, Dr. Langdon Down reported on a syndrome (which now bears his name) that is currently recognized as being the result of a trisomy of chromosome 21. At the time of his report, Dr. Down, of course, had no notion of chromosomes. Indeed, though his theoretical understanding was fundamentally flawed, Down's clinical observation has been remarkably robust. As time went on, more and more syndromes of ID were identified. It became clear that ID could result from a range of risk factors, including problems related to the developing fetus, and ranging from genetic factors (Down syndrome) to exposure to toxins in utero (fetal alcoholism) to maternal infections (congenital rubella). As noted subsequently, advances in genetics have led to an explosion in the recognition of such syndromes, often with a very precise understanding of their cause (3,23).

In recent years, several developments have substantially changed the approach to treatment and prevention of ID in the United States. Beginning in the 1960s, there has been increased emphasis on the care of persons in their homes and communities. The trend toward deinstitutionalization reflects various concerns about the effects of prolonged institutionalization and has led to creation of many community services. This movement has been further stimulated by the mandate of the U.S. federal government that schools provide appropriate education for all children with disabilities, within integrated settings when possible. In the United States, many students with ID are largely or entirely integrated into classrooms with typically developing age mates, although there are marked state-to-state variations (24), and the benefits of mainstreaming are the focus of some debate (25). It is clear that students with more severe disabilities are most likely to spend their school time in more restricted settings.

One unfortunate aspect of current practice has been the often complete separation of services for those who are mentally ill from those who are mentally retarded. Although administratively useful, this approach has made provision of high-quality psychiatric care even more difficult to obtain for many persons with ID. With renewed interest in the field of "dual diagnosis" of ID and psychiatric disorders (26),

we can only hope that this separation will soon be ending.

PREVALENCE AND EPIDEMIOLOGY

The use of both subnormal intellectual functioning and deficits in adaptive behavior in the definition of ID has important implications for epidemiology. If only the IQ criterion is used, the expectation, based on the normal curve, would be that about 2.3% of the population should exhibit the condition. This number is significantly decreased, particularly in adulthood, if the adaptive criterion is included. For example, in the Isle of Wight study, Rutter et al. (27) noted that, in 9- to 11-year-old children, about 2.5% would be classified as mentally retarded if IQ were the sole criterion. But if the prevalence were based only on those receiving services, this rate would be cut almost in half (1.3%) (Fig. 5.2.2.2). The drop in cases based on inclusion of IQ and adaptive skills is more common among those with mild ID (28,29); these children (and adults) may, however, need services and support at times of stress (30,31). As children, such persons are more likely to have academic and behavioral problems (27).

Additional findings have also recently been reported from large-scale epidemiologic studies (32). For individuals with severe ID, prevalence levels mostly converge on 3 to 4 children per 1,000; for mild ID, rates range wildly from 5.4 to 10.6 children per 1,000 (29,30). Studies also examine correlates of ID as gender, age, and social economic status (SES). More boys than girls have ID, and rates of ID are generally low in the early years, peak at around 10 to 14 years, and decrease slightly in the late-school years and markedly during adulthood. Individuals of lower SES and of ethnic minority groups (in several cultures) (13) also show higher-than-expected rates of ID.

CLINICAL DESCRIPTION

Clinical Features

Associated clinical features vary depending on several factors, most importantly the cognitive level. Persons with severe and profound ID come to diagnosis at a younger age, more often exhibit related medical conditions, may exhibit dysmorphic features, and have a range of behavioral and psychiatric disturbances. In contrast, persons with mild ID often come to diagnosis much later (typically when academic demands become more prominent in school), are less likely to have medical conditions that could account for the ID, and usually are of normal appearance without dysmorphic features. In this latter group, although rates of psychopathology are increased relative to nondisabled populations, the range and nature of problems seen are fundamentally similar to those in normative samples (3). Persons with moderate levels of ID are intermediate between these two extremes. It is well recognized that the nature of associated psychiatric and behavioral disorders undergoes a marked shift between the mild and more severe levels of ID (33). Chapters 3.2.2 and 3.3.3 discuss some aspects of genetic contributions to intellectual disabilities.

ASSOCIATED PSYCHIATRIC AND BEHAVIORAL PROBLEMS

A growing body of work focuses on psychiatric and behavioral difficulties relative to specific genetic causes (34,35). Features have been identified that are highly

frequent to specific syndromes, such as hyperphagia and compulsivity in Prader–Willi syndrome (36), attentional and social problems in fragile X syndrome (37), inappropriate laughter in Angelman syndrome (38), the unusual cry in 5p– syndrome (39), and the self-hug in Smith–Magenis syndrome (40). In some instances, aspects of syndrome expression have even been related to the genetic features of the syndrome, such as the severity of ID in fragile X syndrome (41,42) and the type and severity of maladaptive behaviors in Prader–Willi syndrome (43–45). Furthermore, some of these connections between genetic disorder and behavioral outcome appear unique to a single syndrome, whereas others are "shared" among two or more syndromes (46–48). Thus, in some instances, features are relatively syndrome specific, such as the unusual hand-washing stereotypies of Rett syndrome (49), or the extreme hyperphagia in Prader–Willi syndrome (50). More often, however, features are shared in two or more conditions. Thus, attentional problems are frequent in fragile X, Williams, and 5p– syndromes (51,52).

Somewhat paradoxically, for many years the diagnosis of ID tended to cause clinicians and researchers to overlook the presence of associated psychiatric and behavioral problems; such difficulties, when noted at all, were assumed to be a function of the ID. This "diagnostic overshadowing" (53) remains a problem in clinical practice (54). Although more clinicians and researchers are being specifically trained to work with this population, the separation of ID and mental health services in most states is a further obstacle to appropriate identification and treatment of mental disorders.

Although rates vary, as many as 25% of persons with ID may have significant psychiatric problems; these rates are much higher if persons with salient behavior disorders are included (55). Problems are invariably seen in children who present clinically (56), whereas rates are lower, from 10% to 15%, in more population-based studies, including two large-scale medical record surveys of all clients served in New York and California (57,58). Rates that fall between these two extremes, from 30% to 40%, are found in other studies based on informant checklists of behavior problems of children or adults in nonreferred samples (59).

Persons with ID experience the same range of psychiatric problems as seen in the general population (60), but prevalence rates for specific disorders vary widely. Some of this variability may be associated with different methods for determining "caseness," with common approaches including record reviews, behavioral checklists, and, to a lesser extent, direct interviews (61–64). An additional concern is that although some researchers assess DSM- or ICD-based diagnoses, others identify maladaptive features commonly seen in the general population (e.g., inattention or sadness), whereas still others focus on a narrow range of behaviors seen primarily in persons with ID (e.g., stereotypies or self-injury) (47).

For example, rates of schizophrenia or psychosis in persons with ID range from 1% to 9% among nonreferred samples and 2.8% to 24% in referred samples.

Although variable, these rates are much higher than the 0.5% to 1% of the general population with schizophrenia (1). Rates for depression vary from 1.1% to 11% across nonreferred and clinic samples of persons with ID, and rates of attention deficit hyperactivity disorder range from 7% to 15% in children with ID, a finding that contrasts with the 3% to 5% estimate among children in general (1). Patterns of psychopathology also differ across persons with or without ID. Relative to the general population, for example, people with ID are more likely to show psychosis, autism, and behavior disorders and are less apt to be diagnosed with substance abuse and affective disorders (35,36).

ASSESSMENT OF PSYCHIATRIC DISORDERS

As researchers increasingly began to appreciate the scope of problems in persons with ID, they also developed various ways of assessing these problems. Some work has been devoted to the development of specialized rating scales and surveys; most of these measures are geared specifically for persons with ID and have well-developed psychometric properties (65). Among the more widely used are the Aberrant Behavior Checklist (66), Reiss Screen (67), and Developmental Behaviour Checklist (62). A tradeoff in using these scales is that, although they are sensitive to the unique concerns of those with ID, they are not necessarily compatible with DSM or ICD psychiatric diagnoses. Further, because each scale has a different set of items and factor structures, these differences may ultimately contribute to inconsistent findings across studies (61).

At the same time, other researchers have taken issue with the applicability of traditional DSM or ICD diagnoses for persons with ID (33). Many of these concerns relate to the psychiatric interview itself, including acquiescence bias, and the limited abilities of many persons with ID to answer questions about the onset, duration, frequency, and severity of symptoms (36). In response to these challenges, several groups have adapted traditional DSM or ICD criteria for persons with developmental delay (3,60), whereas others have designed interview schedules specifically for those with ID, including the Psychiatric Assessment Schedule for Adults with Developmental Disability (68). Direct interviews with both respondents and informants result in fewer cases of missed diagnoses (69). Still others advocate a more functional analysis of challenging behavior (70).

CAUSES OF INCREASED PSYCHOPATHOLOGY

Although the field has done well with assessment and diagnostic issues, less progress has been made in advancing theories on why persons with ID are at heightened risk of psychopathology in the first place. Many reasons have been discussed over the

years and most fall within the “biopsychosocial” spectrum. Yet a comprehensive model of “dual diagnosis” is lacking, in part because researchers cannot simply apply existing risk factors for psychopathology in the general population to the unique characteristics of those with ID (71). In addition, the causal direction of most risk factors is unclear. Poor peer or social relations, for example, may be a precursor of psychopathology or a consequence of disruptive behavior.

Even so, some advances have been made, and heightened psychopathology in persons with ID has now been linked to specific biopsychosocial problems. Biologically, these include increased rates of seizure disorders (72,73), abnormal neurologic functioning that in most cases is undetected (74,75), high rates of sensory or motor impairments among persons with ID (76), biochemical or neurologic anomalies associated with unusual behaviors such as severe self-injury (77), and genetic causes that carry higher than usual risks of certain maladaptive or psychiatric vulnerabilities (78).

Psychological risk factors include the following: aberrant personality styles, including an outer-directed orientation and being too wary or disinhibited with others (79,80); atypical motivational styles or abnormal levels of sensitivity to basic human drives such as the need for attention or acceptance (81); increased risk of failure experiences, which may lead to learned helplessness, low expectancies for success, and depression (81,80); more global and less differentiated self-concepts that may lead to more sweeping negative evaluations of the entire self instead of not liking just one aspect of one’s self (82); and reinforcement of negative behaviors, leading to more entrenched maladaptive behavior or interactions (83).

Finally, specific social risk factors include the following: poor communication or assertiveness skills, which may lead to increased frustration and acting-out behavior (84); social strain or stressful social interactions, more strongly correlated with psychopathology than low levels of social support (85); social stigma, with a subsequent negative impact on daily living, adjustment, and esteem (30); peer rejection and ostracism and, among children, atypical patterns of friendship with typically developing children (86); compromised “social intelligence,” or inappropriate responses to social cues, that may exacerbate stigma and isolation from others (87); heightened risks of exploitation and abuse, which may worsen behavioral or emotional problems (88,89); and family stress, including low levels of emotional, service, or financial support to families (90).

GENETIC RISK AND PSYCHOPATHOLOGY

As previously noted, a comprehensive model has yet to be developed that identifies the relative importance of these many risk factors. To date, research aimed at doing so has generally relied on heterogeneous groups with ID. Yet each of the factors listed earlier can just as easily apply to those with a genetic diagnosis, and

syndrome-specific studies may shed new light on genetic or other mechanisms associated with certain psychopathologic conditions (47,63). The latter are of particular interest as they offer the potential for new treatments.

ETIOLOGY AND PATHOGENESIS

Historically, researchers have used two broad categories to classify persons with ID (13,91). One group has organic causes of their ID and consists of people with known prenatal, perinatal, and postnatal insults. Estimates suggest that approximately one-half of people with ID have known "organic" causes (92). The second group has no clearly identifiable organic cause and is postulated to account for most persons with mild ID. In years past, the terms "sociocultural" or "cultural-familial" retardation reflected the view that nonorganic ID stemmed from environmental deprivation. Although impoverished, chaotic environments may indeed be implicated in a few cases, this theory has generally fallen out of favor as an explanation for the population as a whole. Even so, a complicating factor is that disproportionately more persons with sociocultural ID are poor, from minority backgrounds, and of low IQ parents (92).
FIGURE 5.2.2.3. A: Distribution of Stanford–Binet IQ expected from the normal curve. **B:** Approximate distribution of IQs actually found, with persons having signs of pathologic origin separated from those not having signs of pathologic origin. (From Achenbach T: *Developmental Psychopathology*. 2nd ed. New York, Wiley, 1974, with permission.)

With increased diagnostic precision and with the discovery of new genetic disorders, many workers speculate that more persons with nonspecific delay will receive specific genetic diagnoses in the years ahead. The complex interplay of organic and genetic (including polygenic) factors with sociocultural and environmental factors has been increasingly recognized (93). Progress has been slower in identifying clear neurologic causes in persons with unspecified ID, because most neuroimaging research is conducted with persons with known genetic or other causes (75). However, some persons with nonorganic causes may simply represent the lower end of the normal, Gaussian distribution of intelligence (94,95).

Assuming that nonorganic ID is the extreme end of the normal IQ distribution, then some persons will always belong to this group, even as progress is made in uncovering genetic or neurologic causes for other persons at the same IQ levels (Fig. 5.2.2.3).

In the organic group as well, many unresolved issues remain. Early researchers grouped people together who had different types of organic causes and often compared these heterogeneous groups with those with familial or nonspecific ID. Even today, mixed or heterogeneous groups, consisting of those with known and unknown causes for their delay, predominate in behavioral ID research (23). Yet with the remarkable progress in molecular genetics, and improved diagnostic accuracy, researchers are now much better positioned to examine people with specific genetic causes. Indeed, there are now nearly 1,000 known genetic causes of ID (96), and as many as one-third of all persons with ID have already been diagnosed with a known genetic disorder (97). Further, although genetic and other organic causes are typically seen in persons with severe and profound delay, high functioning persons with Down syndrome, fragile X syndrome, Prader–Willi, Williams, and other syndromes may comprise 10% to 50% of persons with mild ID (93).

With these advances, research on so-called behavioral phenotypes is gaining momentum, including both between-syndrome and within-syndrome designs (23,34,94). Between-group studies help to identify possible unique syndromic behaviors that may accelerate our understanding of gene or brain function. Further, and as shown in Table 5.2.2.2, some syndromes feature unique psychiatric vulnerabilities, including increased rates of obsessive–compulsive symptoms in Prader–Willi syndrome (43), as well as anxiety, fears, and phobias in Williams syndrome (95). Groups without these syndromes can also have these vulnerabilities, albeit much less often. As such, studies on these syndromes hold much promise for differentiating genetic from other pathways to these psychiatric endpoints.

Cognitively as well, some syndromes show distinctive profiles of relative strength or weakness that are not typically seen in studies of persons with mixed or nonspecific causes of ID. As summarized in Table 5.2.2.2, persons with Williams, Prader–Willi, Down, and other syndromes often show distinctive patterns of cognitive strength or weakness. Many people with Williams syndrome, for example, show relative strengths in specific aspects of expressive language, along with pronounced deficits in visual–spatial functioning. Despite visual–spatial deficits, however, many persons with Williams syndrome have a remarkable sparing of facial recognition and memory. Many, although not all, persons with Prader–Willi syndrome show remarkable skills solving jigsaw puzzles, with performances that exceed those of their chronologic age mates (96).

TABLE 5.2.2.2

EXAMPLES OF COGNITIVE AND BEHAVIORAL PROFILES IN SELECTED INTELLECTUAL DISABILITY SYNDROMES

Syndrome	Cognitive Weakness	Cognitive Strengths	Behavioral Profiles
Fragile X	Sequential processing, auditory STM, planning	Verbal LTM-acquired information	Social anxiety, shyness, gaze aversion, inattention, hyperactivity, autism/PDD
Prader–Willi	Sequential processing	Verbal LTM, visual-spatial processing	Hyperphagia, nonfood obsessive-compulsive symptoms, skin picking, tantrums
Williams	Spatial organization, visual motor coordination	Facial recognition, auditory STM, expressive language	Social disinhibition, anxiety, fears, inattention, hyperactivity, hyperacusis
Down	Auditory processing	Visual-spatial processing, expressive language	Noncompliance, stubbornness, inattention, depression and dementia in adults

LTM, long-term memory; PDD, pervasive developmental disorder; STM, short-term memory.

However, most syndromic behaviors appear to be "partially specific" or shared across one or more conditions (46). For example, persons with both fragile X and Prader–Willi syndromes appear to have relative weaknesses in certain short-term memory and sequential processing tasks (50), and inattention and hyperactivity are seen in Williams, fragile X, and 5p– syndromes (51,52,62). These disorders, however, show qualitative differences in symptoms. Inattention in Williams syndrome, for example, may be associated with heightened anxiety and social disinhibition, whereas in fragile X syndrome, these difficulties may be related to hyperarousal and anomalies in the size of the posterior cerebellar vermis and caudate nucleus (98).

Although between-group studies help to identify distinctive syndromic behaviors, within-syndrome studies help to explain individual variation in these behaviors. Researchers now need to identify the genetic, environmental, developmental, and psychosocial factors that help to explain individual behavioral differences in people with the same genetic disorder. For example, the level of cognitive delay in fragile X syndrome is associated with both age and molecular genetic status (42). Similarly, in Prader–Willi syndrome, the frequency and severity of maladaptive behaviors such as skin picking appear to vary across genetic subtypes of this disorder (36).

Whereas research on heterogeneous groups is still necessary, both between-syndrome and within-syndrome studies offer many advantages (35,47). In the long term, work on behavioral phenotypes facilitates the search for gene–brain–behavior relationships, as well as contributing toward a more precise science of ID. In the short term, phenotypic data refine intervention and treatment (99,100). Although many syndrome-specific recommendations for interventions have now been made, the efficacy of these approaches needs to be evaluated, including how they fare relative to more generic interventions.

DIFFERENTIAL DIAGNOSIS

The diagnosis of ID is based on the appropriate assessment of cognitive abilities and adaptive skills; clinical assessment also includes a careful developmental and family history, physical examination, and laboratory studies as appropriate. The clinician should be alert to any medical or environmental conditions that may be associated with developmental disability. For example, a strong family history or certain dysmorphic features in the child should raise the possibility of an inherited condition; a history of significant birth trauma, exposure to environmental toxins, and exposure to marked psychosocial adversity are some of the factors that should be considered.

As noted, the age of diagnosis often varies depending on the severity of the disability, so persons with more severe ID present for clinical assessment earlier than those with mild, or borderline, ID. Careful psychological assessment of the child (Chapter 4.4) is obviously critical. Various other developmental difficulties, notably language and other specific developmental disorders and autism and related conditions, may be associated with some degree of mental disability or may be confused with it. Diagnosis can be complicated because persons with ID can exhibit other developmental problems that can complicate the task of both diagnosis and assessment. For example, children with a marked expressive language disorder often do poorly on a test of intelligence test that is highly verbal. In autism and related disorders, social abilities tend to be the area of greatest weakness (see Chapter 5.2.1). Potential genetic and toxic environmental contributions should also be considered particularly in children with greater degrees of intellectual impairment (see Chapters 3.2.2 and 3.3.3).

TREATMENT

In most developed countries, the treatment of ID has undergone a marked shift over the past few decades. More persons with ID now reside with their families and in their communities. More children now receive services within regular educational settings, and more services are available to support them and their families. At the same time, it is clear that placement in the community is not sufficient in and of itself, and the provision of adequate and appropriate support is critical. This is particularly important for the growing numbers of older persons with ID, many of whom still reside with their aging parents.

In general, treatment planning begins with a consideration of the underlying cause, if one is known, of the ID. In many instances, knowing the cause can guide both medical and psychosocial interventions; indeed, many syndrome-specific parent and professional organizations have published "best practice" guidelines across the

lifespan (e.g., Prader–Willi, Williams, and Down syndromes). However, for disorders that are more rare, such data are lacking.

Medical Treatment

Medically, laboratory studies should be based on the results of a careful history (including family history) and evaluation. Physical examination should include assessment of growth and developmental status as well as observation for facial features or other physical findings that could suggest a specific medical condition. It is sometimes the case that the evolution of the condition provides important clues to its cause, such as in Rett syndrome. Depending on the clinical circumstance, hearing or visual testing may be indicated as are, at times, specific metabolic studies, chromosome analysis (including fragile X testing), neuroimaging or neurologic assessment, skeletal radiography, screening for organic acidurias, associated genetic conditions, and so forth (101,102).

Persons with ID may be at increased risk for certain medical conditions (103). In their review of the Aberdeen cohort of cases, Goulden et al. (104) noted that at least 15% of patients developed epilepsy by adulthood; the risk was increased when associated disabilities were present or when there was a history of postnatal injury.

To some extent, associated medical conditions vary depending on the cause of the ID. Consider Down syndrome, the most common genetic (i.e., chromosomal) cause of ID. Although the median age of death among individuals with Down syndrome has increased from 25 to 49 years over the period from 1983 to 1997 (105), specific medical problems persist for these individuals throughout their lifetimes. Congenital heart defects occur in approximately 50% of newborns with Down syndrome (106,107), and the large majority of these children are hospitalized for heart or other problems (mostly pneumonia, bronchitis, or other respiratory problems), often within the first few months of life (108). Later, children with Down syndrome are more likely than other children to have leukemia, and, by age 40, the plaques and tangles of Alzheimer disease strike virtually all adults with the syndrome (109). Other genetic disorders, notably Prader–Willi syndrome, also show particularly high rates of etiology-related health problems and higher death rates in the young adult and middle-aged years (110).

Cognitive and Adaptive Intervention

Regardless of the origin of ID, accurate assessment of each person's intellectual and adaptive strengths and weaknesses is essential, because specific recommendations for intervention depend on the overall level and profiles of cognitive functioning. Although there are many different models of intelligence (111), investigators generally agree about such basic features of intelligence as the ability to use

conceptual thinking in solving problems and in acquiring knowledge (112). Various IQ tests are now available, and they differ in certain dimensions, such as the degree to which they emphasize language-based problem-solving or short-term memory. Tests differ in other ways as well: some tests include timed tasks, whereas others provide the opportunity for demonstration of tasks by the examiner. As part of the standard administration of test items, the examiner is also able to collect considerable amounts of qualitative information that may be particularly important for treatment.

Some special considerations are involved in assessing persons with ID. To the extent possible, tests should be appropriate for the person's chronologic age as well as her or his levels of receptive and expressive language. In some cases, cultural and other factors also need to be considered. The behavioral problems sometimes associated with ID may pose special problems; particularly if they arise around times of change or frustration.

Assessment of adaptive functioning has the goal of providing a representative picture of the person's typical abilities in home, school, and community environments. In this regard, the goal is somewhat different from that of the intellectual assessment, in which the aim is to obtain optimal performance in a structured and standardized situation. Large discrepancies between intellectual level and adaptive skills suggest that the treatment should include a major focus on acquisition and generalization of adaptive skills.

Various measures of adaptive functioning have been proposed. The most widely used instrument is the Vineland Adaptive Behavior Scales (2), which assess capacities for self-sufficiency in various domains of functioning, including communication (receptive, expressive, and written language), daily living skills (personal, domestic, and community skills), socialization (interpersonal relationships, play and leisure time, and coping skills), and motor skills (gross and fine). The Vineland scales are available as a survey interview, an expanded interview for use in more detailed program planning, an informant-administered rating form, and a teacher rating form.

Psychiatric Treatment

As previously described, persons with ID are at increased risk of psychiatric problems, and these are often a major source of distress to the individual and family and may severely limit opportunities for self-sufficiency and independence (102). Yet these mental and physical health problems are frequently overlooked. Ryan and Sunada (103) report that up to 75% of persons with ID who are referred for psychiatric assessment have undiagnosed or undertreated medical conditions, and nearly 50% receive no psychotropic medications that could have behavioral side effects.

Even though associated psychiatric problems can severely limit personal and social sufficiency, there is often a tendency to neglect or overlook the mental health needs of this population (59). Although some of the many rating scales, checklists, and other instruments for assessment of psychopathology in the general population are applicable, other instruments have been developed that are specific for persons with ID. Psychiatric assessment may entail some modification in usual procedures, particularly for persons with more severe ID, in whom the psychiatric assessment must be comprehensive and multifocal. The presence of associated difficulties (seizures, motor impairments, sensory problems) may further complicate accurate psychiatric diagnosis.

Other Psychosocial Treatment

General quality-of-life issues are receiving renewed attention in the ID field, with particular emphasis on improving how people with ID live, work, and play in inclusive, community-based settings. Most persons with ID benefit from employment or from structured programs that emphasize vocational, adaptive, or socialization skills, long after formal schooling. Indeed, the transition from school to work is a vulnerable point for many persons and their families. Unlike the school years, when special education and related services (e.g., occupational, physical, and speech and language therapies) are typically provided at school under one roof, the services for adults risk being more fragmented. These young adults may particularly benefit from *case coordination,* to avoid becoming isolated or lost between various cracks in services (113).

A particularly troublesome outgrowth of adult service needs concerns residential placements. As individuals with ID live longer lives, our society increasingly needs to deal with who will take care of these individuals when aging parents can no longer do so. Currently in the United States, 526,000 individuals with disabilities are 60 years and over; by the year 2030, that number is expected to triple, to 1.5 million (114). Since over 60% of these individuals live in their parents' home, who will take care of these aging individuals? Such concerns have recently led to a call from more research on adult siblings of individuals with ID (115), as these adult siblings (116) are likely to become tomorrow's caregivers for aging brothers and sisters with disabilities.

OUTCOME AND FOLLOW-UP DATA

As expected, the course and outcome of ID vary considerably, depending on various factors. These include the level of severity of the ID, associated biologic or other vulnerabilities, and aspects of the individual's psychological functioning, family support, and other factors (3). Levels of ability to cope with the demands of daily life

(i.e., adaptive skills) are critical in determining adult outcome. It is also clear that the expectations of caregivers and the provision of intervention services and environmental supports are also important. For persons with known medical causes of ID, certain risks may be present, such as the risk of early development of Alzheimer dementia in persons with Down syndrome (117). Conversely, even when the specific biomedical cause is known, there may be a wide range in ultimate outcome. To simplify the discussion of outcome, we focus the discussion on levels of ID but again emphasize that the outcome in a given individual patient varies considerably, depending on a host of factors.

In mild ID, many children with the condition go on, as adolescents and adults, to make major gains in adaptive functioning and thus may "lose" the diagnosis as they become older. Such persons may be self-supporting, may marry, and may raise families. At the same time, such persons are not without difficulties, because several studies (27,31) show that persons with intellectual deficits who have not required special services in school have higher rates of educational and behavioral problems. In their follow-up study of the Aberdeen cohort of children first seen at 9 to 11 years of age and then followed up at the age of 22 years, Richardson and Koller (118) report that more than 75% no longer require services as adults, although only about 25% of the entire group are judged to be functioning adequately in all areas. Mild ID is likely to be diagnosed only at the time of school entry, that is, when academic demands increase. As discussed previously, persons from backgrounds of social disadvantage or adversity and from certain minority groups are more likely to be represented in these cases.

As adults, persons with moderate levels of ID (IQ 40 to 55) typically have more serious impairment. It is common for such persons to need services as adults. At this, and lower, levels of cognitive functioning, specific medical causes are more likely to be identified, and minority group membership and psychosocial adversity in the family are less frequent. The prognosis for adult self-sufficiency is more guarded, although many persons can live semiindependently or with partial support (119).

For persons with severe or profound retardation, case identification may occur in infancy or early childhood. Generally, high levels of supervision and support are required during the person's life. Goals for these patients include facilitating self-care and other skills as far as possible. Associated medical problems and behavioral difficulties are frequent. Communication skills may be impaired and are a further source of disability.

Legislation, legal decisions, and some important social policy changes have markedly changed the provision of remedial programs. The provision of early diagnosis and intervention and the availability of community-based resources and educational interventions within public schools have dramatically improved the care of persons with ID as well as overall outcome.

PREVENTION

Estimates of recurrence risk vary depending on the situation, ranging from instances in which a clear genetic origin can be identified (e.g., fragile X syndrome) to those in which the difficulties appear to be of nongenetic origin (e.g., congenital rubella). When no specific cause is identified, estimates of recurrence risk vary considerably, such as between 3.5% and 14% for the siblings of a boy with ID (120). For some disorders, such as autism, there has been a growing appreciation of genetic factors, and it now appears that, for parents who have one child with autism, the risk of having a second child with autism is between 2% and 10% (121). Siblings of children with ID who are not themselves affected may be at increased risk of other difficulties, due to increased family and personal stress, although data are sorely needed on the range of both positive and negative outcomes in these siblings (122). Support for siblings, and for their parents, is an important element of long-term treatment planning (3).

RESEARCH DIRECTIONS

Several issues will likely dominate the research agenda for the coming decade. They include the interplay between genetic and environmental (including psychosocial) risk factors in the origin of ID as well as the study of basic neural mechanisms (94). Understanding of basic processes that underlie phenotypic expression, including various forms of psychopathology, offers the opportunity to advance knowledge more generally about mechanisms of disorder. Although many advances in the care and treatment of persons with intellectual deficiency have been made, studies of treatment methods remain an important priority. Identification of genetic contributions (particularly for single gene disorders) and specific mechanisms likely will hasten development of more targeted treatments approaches; this is already happening in some conditions like fragile X and, in turn, these may have implications for other disorders as well (123).

CHAPTER 5.2.3 ■ LEARNING DISABILITIES

ELENA L. GRIGORENKO

Fundamentally, the concept of learning disabilities (LD) enabled society to identify and serve children demonstrating unexplained school failure in a way that was not possible before the LD category was introduced in 1968 and legally recognized in 1969. The LD category replaced a variety of loose qualifiers such as "slow," "backward," and "feeble-minded" learner, among others. This public law, which ensures that students with LD are provided with Free Appropriate Public Education (FAPE) that is tailored to their individual needs has undergone a number of editions; its current version is known as the "Individuals with Disabilities Education Improvement Act" (IDEIA or IDEA,[1] used interchangeably, or Public Law 108–446 signed in 2004). It has included the category of LD in all of its editions, yet the identification of LD has been surrounded by controversy since the inception of this diagnostic category (1–3). This controversy, in many ways, is still a mark of the field.

In current practice, the LD label typically assumes the following. Under typical circumstances, LD are not diagnosable prior to the child's engagement with schooling and the opportunity to master key academic competencies. It is presumed that in school, a child is assigned tasks that are grade appropriate. These tasks suppose some degree of variability in children's performance; these assumptions constrain the definitions of acceptable and worrisome variability in performance. When the child's performance consistently falls out of the acceptable range in one or more academic subjects, then the child becomes the focus of intense observation and documentation and is referred for evaluation to appropriate professionals (e.g., educational psychologists, school counselors, clinical psychologists, neurologists, pediatricians, and psychiatrists). An important qualifier here is that such observation, documentation, and evaluation are considered only for children whose performance is below that expected based on their general capacity to learn; thus, the concept of "unexpected" school failure is central to the definition of LD. If something is "unexpected," then it could not have been predicted (or, at the minimum, predicted accurately). There are important safeguards that are used to minimize the risk of missing such unexpected events. First, although a diagnosable manifestation of LD can be unexpected, there are numerous risk factors that forewarn the relevant professionals about a possible onset of LD. These risk factors may be assessed and monitored as early as 3 years of age and are typically defined through various psychological processes that have to be recruited into the construction of a new academic skill. Second, public laws have special provisions—the Child Find Section of the IDEA (Child Find), Section 504 of the Rehabilitation Act of 1973, as amended (Section 504), and Title II of the Americans with Disabilities Act of 1990

(Title II)—that require local education agencies to identify and serve children with such "unexpected" difficulties in the acquisition of academic skills while in school.

When reports on the child's performance in the classroom, testing results, and clinical evaluations are compiled, the child and his or her family are referred to a committee (Planning and Placement Team), which determines the child's eligibility for individualized special education services. If eligibility is established, an individualized education program (IEP) is created for that child. The IEP refers to a specific diagnostic label carried by the child and cites the proper category of public laws that guarantees services for an individual with such a diagnosis.

DEFINITION

The definition that currently drives federal regulations was produced by the National Advisory Committee on Handicapped Children in 1968 and subsequently adopted by the U.S. Office of Education in 1977 (4). This definition has remained virtually unchanged in the IDEA (Title I, Part A, Sec. 602, §30). According to this definition, "*specific learning disability* means a disorder in one or more of the basic psychological processes involved in understanding or in using language, spoken or written, which may manifest itself in an imperfect ability to listen, think, speak, read, write, spell, or to do mathematical calculations. The term includes conditions such as perceptual handicaps, brain injury, minimal brain dysfunction, dyslexia, and developmental aphasia. The term does not include learning problems which are primarily the result of visual, hearing, or motor disabilities, of intellectual disability, or emotional disturbance, or of environmental, cultural, or economic disadvantage" (5).

The *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5 (6)) does not use the term learning disabilities, but makes a reference to the term learning disorders. According to the DSM-5, "specific learning disorder can only be diagnosed after formal education starts but can be diagnosed at any point afterward in children, adolescents, or adults, providing there is evidence of onset during the years of formal schooling (i.e., the developmental period). No single data source is sufficient for a diagnosis of specific learning disorder. Rather, specific learning disorder is a clinical diagnosis based on a synthesis of the individual's medical, developmental, educational, and family history; the history of the learning difficulty, including its previous and current manifestation; the impact of the difficulty on academic, occupational, or social functioning; previous or current school reports; portfolios of work requiring academic skills; curriculum-based assessments; and previous or current scores from individual standardized tests of academic achievement" (p. 70). Of interest here is that this is one of the very few categories of the DSM-5 where a reference is made explicitly to psychological tests, although, as stated, DSM-5 does not provide specific guidelines as to what "substantially below"

means. Thus, DSM-5 implicitly refers to evidence-based practices as they exist in the field. The problem, of course, is that there are multiple interpretations of these best practices (see discussion following). Yet, assuming there are consistent and coherent guidelines in place for establishing the diagnosis of LD, the DSM-5 classifies types of LD by referencing the primary academic areas of difficulty. The classification includes three specific categories: specific learning disorder with impairment in reading (315.00, F81.0), written expression (315.2, F81.81), and mathematics (315.1, F81.2). A common practice in the field is to view a diagnosis of a learning disorder as established by DSM-IV as an equivalent to "specific learning disability," which qualifies a child for special services under federal regulations. Of particular importance is the recognition that LD are lifelong disorders; however, reassessments are needed at meaningful intervals to trace the developmental transformations of LD.

HISTORY

The introduction of the concept of LD is typically credited to Samuel Kirk (then a professor of special education at the University of Illinois), who, while presenting at a conference in Chicago on April 6, 1963, proposed the term *learning disability* to refer to children who have disorders in development of language, speech, reading, and associated communication skills. The category was well received and promoted shortly thereafter by an established parent advocacy group known as the Association for Children with Learning Disabilities. Prior to the formal introduction of this concept, the literature had accumulated numerous descriptions of isolated cases and group analyses of children with specific deficits in isolated domains of academic performance (e.g., reading and mathematics) whose profiles were later reinterpreted as those of individuals with specific LD (e.g., specific reading and math disabilities). It is those examples in the literature and the experiences of many distressed parents desperate to find adequate educational support for their struggling children that, in part, resulted in the creation of the field of LD as a social reality and professional practice (7). The subsequent accumulation of research evidence and experiential pressure led to the formulation of legislation protecting the rights of children with LD.

Congress enacted the *Education for All Handicapped Children Act* (Public Law 94–142) in 1975 to support states and educational institutions in protecting the rights of, meeting the individual needs of, and improving the results of schooling for infants, toddlers, children, and youth with disabilities, and their families. This landmark law is currently enacted as the IDEA, as amended in 2004. In its 2004 version, the law was tightly associated with the No Child Left Behind (NCLB) Act. As NCLB was replaced in 2015 by the Every Student Succeeds Act (ESSA), major changes are expected in IDEA as well, as it is due for reauthorization. The importance of this law is difficult to overstate given that, prior to its enactment, in 1970, US schools

provided education to only one in five children with disabilities (8). By the school year 2013–14, the number of children served under IDEA was 6.5 million, or 13% of the total public school enrollment. Approximately 35% of these students were classified as LD (9).

In its 2004 amendment, IDEA recognizes 13 categories under which a child can be identified as having a disability: autism; deaf-blindness; deafness; emotional disturbance; hearing impairment; intellectual disability; multiple disabilities; orthopedic impairment; other health impairment; specific learning disability; speech or language impairment; traumatic brain injury; and visual impairment, including blindness. Notably, LD as described above in IDEA are referred to as "specific learning disabilities" (SLD, hereafter, LD) to emphasize the difference between children with SLD and those with general learning difficulties (GLD) characteristic of other IDEA categories (e.g., autism and intellectual disability). The consensus in the field is that children with LD possess average to above-average levels of intelligence across general domains of functioning, but demonstrate specific deficits within a narrow range of academic skills. Finally, as stated above, exclusionary factors have been central to diagnoses of LD (10); a child cannot be diagnosed with an LD unless other factors such as other disorders or lack of exposure to high-quality age-, language-, and culture-appropriate educational environments have been ruled out. To rule out the lack of exposure to high-quality environments as an exclusionary factor, the 2004 amendment of IDEA introduced the concept of Response to Treatment Intervention (RTI)—"individual, comprehensive student-centered assessment models that apply a problem-solving framework to identify and address a student's learning difficulties" (11) (p. 483).

EPIDEMIOLOGY

There are two main sources for obtaining estimates for prevalence rates of LD. The first and most obvious one is linked to the number of children served under this category of IDEA. Figure 5.2.3.1 provides relevant data. When these data are mapped on the total number of children in the United States, although the number fluctuates from year to year, the average estimates of prevalence rates for LD are around 5% to 6% of the total school-age population.

Yet it is important to note that prevalence rates vary substantially from district to district and from state to state. For example, in 2011, of all students receiving special education services, those who received them under the category of LD comprise 14.1% in Kentucky compared with 60.4% in Iowa. Thus, based on these numbers, the prevalence rates of LD in Iowa are about 4.2 times as high as in Kentucky, two states not very far apart geographically! This observation stresses the mosaic-like situation of LD diagnosis: there is no unified approach to these diagnoses across different local education agencies in the United States.

When IDEA-related prevalence rates are considered, LD are diagnosed more frequently in boys than in girls (in 2013, these numbers were 9% and 6% for boys and girls aged 6 to 17, respectively). Of interest is that, in 2013, there were no significant differences in the rate of LD by race or Hispanic origin, although such differences (12) (i.e., LD was diagnosed more frequently in underrepresented minority groups than in Asian American or White) were often observed prior to the 2004 reauthorization.

The second source for these rates is research studies. Per results from these studies, it is assumed that although up to 10% to 12% of school-age children show specific deficits in selected academic domains, high-quality classroom instruction and supplemental intensive small-group activities can reduce this number to approximately 6% of children. It is assumed that these 6% will meet strict criteria for LD and will need special education intervention.

It is important to note that most of the research in the field of LD is disproportionally conducted with reading and, correspondingly, specific reading disability (SRD). Although there has been an exponential growth of the literature on mathematics (and specific math disability [SMD]) and writing (and specific writing disability [SWD]), the research on reading and SRD is where the frontiers of LD science currently are.

To illustrate, according to the results of current research on early reading acquisition, 2% to 6% of children do not show expected progress even in the context of the highest-quality evidence-based reading instructions. Based on US national data, the risk for reading problems as defined through failure to reach age- and grade-adequate milestones ranges from 20% to 80%. Specifically, data from the National Assessment of Educational Progress (http://www.nationsreportcard.gov/) 2015 show that only 36% of 4th, 34% of 8th, and 37% of 12th graders perform at or above a proficient level in reading, that is, possess the adequate reading skills required for the completion of grade-appropriate educational tasks. Similarly, only 40% of 4th, 33% of 8th, and 25% of 12th graders perform at or above a proficient level in math. The numbers for writing are available only for 2011 and only for 8th and 12th graders and they are 27% and 27%, respectively. However, it is clear that far from all of the children who perform below the proficiency level have SRD, SMD, or SWD. The majority of these children underachieve, most likely because of inadequate educational experiences or causes other than SRD.
FIGURE 5.2.3.1. The absolute numbers (*left axis,* shown in *bars*) and percentage of children (*right axis*) diagnosed with SLD, out of the total number of children in special education in the United States, from 1976 to 2014.

Some changes in the 2004 version of IDEA were invoked directly because of concerns regarding the overidentification of students as having LD. The category of LD has often been the largest single category of children served under IDEA. The reality of everyday practices in school districts was such that most diagnoses prior to the 2004 reauthorization were based on so-called aptitude–achievement discrepancy criteria (AADC), which required a severe discrepancy between IQ and achievement scores (e.g., two standard deviations, 2 years of age equivalence), although IDEA had never specifically required a discrepancy formula. Correspondingly, it has been argued that these discrepancy-based approaches are flawed and might have led to overidentification, especially among minority youth (13). In light of this hypothesis, IDEA 2004 emphasizes that there is *no* explicit ability-achievement discrepancy requirement for the diagnosis of LD. As a possible alternative approach for identification and diagnosis, IDEA 2004 states that local educational agencies may use a child's RTI in lieu of the classification processes. A local educational agency (e.g., a school) may choose to administer to the child in question an evidence-based intervention program and, depending on the child's response to this program, determine his or her eligibility for special education services under IDEA.

Specifically, the statutory language of the IDEA 2004 states:

(6) Specific Learning Disabilities.

(A) In general.

Notwithstanding section 607(b), when determining whether a child has a specific

learning disability as defined in section 602, a local educational agency shall not be required to take into consideration whether a child has a severe discrepancy between achievement and intellectual ability in oral expression, listening comprehension, written expression, basic reading skill, reading comprehension, mathematical calculation, or mathematical reasoning.

(B) Additional authority.

In determining whether a child has a specific learning disability, a local educational agency may use a process that determines if the child responds to scientific, research-based intervention as a part of the evaluation procedures described in paragraphs (2) and (3). [§614(b)(6)].

As a consequence of this language, although AADC has been and continues to remain the common, although not required, practice for local educational agencies, there is a new "entry point" for RTI.[2] Moreover, as the IDEA language is rather ambiguous and alternative (to RTI) research-based approaches to the identification of LD are permitted, such approaches have been developed since 2004. One such approach is the Pattern of Strengths and Weaknesses (PSW) (14), which attempts to identify a core cognitive processing deficit (or a combination of deficits) as a source of LD. Yet, although present in the literature, this approach is considerably underresearched, compared to either discrepancy criteria or RTI.

Needless to say, these changes are of great theoretical and practical importance. A recent review of LD regulations and guidelines utilized in 2013 by all 50 of the United States and the District of Columbia (3) revealed a quilt-like variability of the interpretation of the IDEA across the United States. Specifically, with regard to the AADC, 67% of states allow and 20% of states explicitly prohibit its use. Approximately 16% of states require the sole use of RTI models and there are considerable differences in how this requirement is implemented. About 50% of states do not allow the use of PSW models, and most states allowing these models provide little information regarding ideal identification practices.

The implementation of RTI since the introduction of IDEA 2004 has generated much data. These data and their analyses have led to a number of observations. Specifically, although the field readily recognizes that the overall intentions and goals of RTI are laudable, (1) the empirical data for evidence-based intervention are rather inconsistent (again, it is more so for mathematics and writing, than reading); (2) the implementation of the RTI model is complex at best, driven in part by nonoverlap of different identification models and, in part, by inadequate teacher training; and (3) evidence of the power of RTI to prevent LD or introduce early identification is weak. It is because of these complexities that the concept of RTI was not included in the DSM-5. The DSM-5's requirement for "6-month persistence, despite targeted intervention" is there as an exclusionary criterion (i.e., to rule out the influence of inadequate instruction and to broadly view targeted intervention as any

type of instruction, at home, school, or specialized services), not as a reference to RTI (15).

ETIOLOGY

There is a consensus in the field that LD arise from intrinsic factors and have neurobiologic bases, specifically atypicalities of brain maturation and function that are rooted in the genome. There is a substantial body of literature convincingly supporting this consensus and pointing to genetic factors as major etiologic factors of LD. The working assumption is that these genetic factors affect the development, maturation, and functional structure of the brain, which in turn, influences cognitive processes associated with LD. Yet, the field is acutely aware that a number of external risk factors, such as poverty and lack of educational opportunities, affect patterns of brain development and function and, correspondingly, might worsen the prognosis for biologic predisposition for LD or act as a trigger in LD manifestation.
FIGURE 5.2.3.2. The componential view of reading.

Although this model, in main strokes, appears to be relevant to all LD, far more research on relevant genes and brain structure and function is available for children with SRD (16) than for any other LD. Thus, here illustrative findings are presented from SRD; there are comprehensive reviews reflecting the state of the field for SMD (17) and SWD (18).

Multiple methodologic techniques (e.g., DTI, EEG, ERP, (f)MRI, MEG, PET, TMS, to name a few[3]) have been used to elicit brain-reading relationships. When data from multiple sources are combined, it appears that a developed, automatized skill of reading engages a wide, bilateral (but predominantly left hemispheric) network of brain areas passing activation from occipitotemporal, through temporal (posterior), toward frontal (precentral and inferior frontal gyri) lobes. The process of reading is multifaceted and involves the evocation of orthographical, phonologic, and semantic representations (Figure 5.2.3.2) that, in turn, call for the activation of brain networks participating in visual, auditory, and conceptual processing.

Indeed, a recent meta-analysis synthesizing age-related commonalities and differences in brain activation patterns elicited in fMRI studies of reading in children and adults revealed both universal and specific patterns (Figure 5.2.3.3). Common patterns engaged left ventral occipitotemporal, inferior frontal, and posterior parietal regions. Children-specific patterns engaged left superior temporal and bilateral supplementary motor regions. Adult-specific patterns engaged bilateral posterior occipitotemporal/cerebellar and left dorsal precentral regions. Thus, imaging studies underscore both the distributed nature of reading-related brain networks as well as their malleability attributable to the maturation and automatization of reading-related skills. Globally speaking, the mastery of reading is marked by progressive, behaviorally modulated development of the left and progressive disengagement of the right hemisphere. In addition, there appears to be a shift of regional activation preferences: The frontal regions are used by fluent more than by beginning readers, and readers with difficulties activate the parietal and occipital regions more than the frontal regions.
FIGURE 5.2.3.3. Surface renderings of maps of the brain circuitry for reading. Light gray indicates the overlapping areas of activation, medium gray—the areas specific to children, and dark gray—the areas specific to adults.

In an attempt to understand the mechanism of the “deficient” pattern of brain activation while engaged in reading, researchers are looking for genes that might be

responsible, at least partially, for these observed differences in functional brain patterns. This search is supported by a set of convergent lines of evidence (19–21). First, SRD has been considered a familial disorder since the late 19th century. This consideration is grounded in years of research into the familiality of SRD (similarity in the skill of reading among relatives of different degrees), characterized by studies that have engaged multiple genetic methodologies, specifically twin, family, sib-pair, and case-control designs. Although each of these methodologies has its own resolution power with regard to obtaining corresponding estimates of relative contributions of genes and environments, all methodologies have produced data that unanimously point to the genome as the main source of individual differences in reading and of the manifestation of SRD.

Today, it is assumed that multiple genes contribute to the biologic risk factor that forms the foundation for the development of SRD (Figure 5.2.3.4). Specifically, nine candidate regions of the human genome have been implicated. These regions are recognized as SRD candidate regions; they are abbreviated as DYX1–9 (DYX for dyslexia, a term often used to refer to SRD) and refer to the regions on chromosomes 15q, 6p, 2p, 6q, 3cen, 18p, 11p, 1p, and Xq, respectively. Each of these regions harbors dozens of genes, and some of them have been named as risk genes for SRD. These genes are: two for the 15q region, *DYX1C1* and *SEMA6D;* two for the 6p region, *KIAA0319* and *DCDC2;* two for the 2p region, *C2Orf3* and *MRPL19;* and one for the 3cen region, *ROBO1.* Although the field has not yet converged on “firm” candidates, it is remarkable and of scientific interest that of the current candidate genes for SRD, five genes (*DYX1C1, SEMA6D, KIAA0319, DCDC2,* and *ROBO1*) are involved in biologic functions of neuronal migration and axonal crossing. Thus, all these genes are plausible candidates for understanding the pattern of brain functioning in SRD. Yet, there are caveats. Specifically, until now, three genome-wide association studies (GWAS) (22–24) have been carried out and none have identified, in an unbiased manner, any of these candidates. Moreover, other genes known to be associated with a variety of cognitive processes, have been shown to be associated with reading and other cognitive functions, questioning the specificity of the genetic sources of individual differences for variation in reading as well as in related brain functions (25,26).
FIGURE 5.2.3.4. Genomic regions of interest for specific reading disability (SRD).

DIAGNOSIS AND CLINICAL FEATURES

As stated earlier, it is crucially important in a diagnosis of LD to establish the "typical" intellectual performance of the child and to document that the child's performance in the area of difficulty (i.e., reading, writing, or mathematics) does not correspond to what would be expected given average ability level. Although this general principle is relatively easy to grasp, the field of LD has, since its inception in the early 1960s, struggled with establishing specific steps that prescriptively should lead to the establishment of the diagnosis.

As mentioned earlier, prior to the 2004 reauthorization of IDEA, the most common way of establishing an LD diagnosis was the AADC. Historically, the introduction of the discrepancy between ability and achievement as a criterion for LD in the 1977 law was not based on empirical research, but rather driven by a need for a more objective approach to the diagnosis than those commonly used and largely discredited at the time (27). Two decades of research and practical explorations of the discrepancy model have resulted in it being discredited from points of view of theory, reliability of diagnosis and classification, robustness of implementation, and treatment validity. In response to the overwhelming amount of evidence for the inadequacy of the discrepancy model, however realized (through psychometric

indices, age equivalences, regression approaches, or expert opinions), a number of alternative models have been proposed. The major dividing line between these new models and previous discrepancy-based models is in their theoretical orientation. Previous diagnostic models attempted to identify children diagnosable with LD by looking for characteristic cognitive deficits, so that an intervention could be delivered to children with such deficits, whereas modern models argue for the need to deliver the best pedagogical practices to all children and then best remediation-intervention approaches to those children who do not respond well to good teaching.

In its most general form, the RTI model has a number of features. First, the performance of the student in question is compared with the performance of his/her immediate peers on academic tasks. Specifically, RTI assumes tracking the academic performance and the rate of growth for all students within a given class, with a goal of identifying those students in a class whose performance differs from that of their peers both in absolute (level) and relative (rate of growth) terms. Second, the model is structured primarily by intervention, so that students identified by these means are offered individualized accommodations and interventions with a goal of maximizing the effectiveness of the learning environment for a given student in need. Third, the model is multilayered, so that each layer offers an opportunity for the further differentiation and individualization of education for students who need it. Typically, three layers are recommended. The first tier covers the regular classroom environment; the second tier is characterized as "supplemental" to tier 1; and tier 3 is "intensive," "individualized," and "strategic." Fourth, only when these multilayered attempts to modify the regular classroom pedagogical environment have proved unsuccessful is the prospect of establishing an LD diagnosis considered. In summary, a child could be identified as having an LD if he or she consistently fails to perform at a level and rate of progress comparable with the child's peers in general education, after having experienced and participated in an evidence-based intervention.

As per the 2004 reauthorization of IDEA, local educational agencies have some choice in selecting diagnostic models, which has resulted in a variety of LD identification models throughout the United States. Specifically, the federal law has permitted the utilization of an RTI approach for over a decade and some states have mandated it. Similarly, some states opened up to the PSW model. So, has either RTI or PSW proven to be better than AADC for the identification of LD? The bottom line is that opinions (and data) vary. Specifically, some researchers assert that an RTI approach does indeed offer a superior approach to LD identification, because, in part, this identification is embedded in the educational process and is instructive, if nothing else, for providing accommodations and services (1). Congruently, there is an argument that the focus on both assessing and remediating specific cognitive processes, as proposed by the PSW model, does not pan out to be advantageous (28). Yet, there are also multiple criticisms of RTI and suggestions that the true solution

lies in combining elements of RTI and PSW approaches (29), as they inform identification differentially and have different roles in answering questions of the *why* LD and *how* to remediate it.

RELEVANT THEORETICAL MODELS AND CONSIDERATIONS

As mentioned earlier, the literature on LD is uneven, with the vast majority of it relating to SRD, although within the last few years much progress has been made with regard to SMD and SWD. Although psychological models of other LD have been developed, here only those for SRD are exemplified for illustration purposes.

So far, there have been only generic references to the disruption of both the acquisition and mastery of reading skills that constitutes the texture of SRD. When this generic reference is closely considered, another massive body of literature materializes: (1) cognitive psychology literature (30) on the types of representation of information involved in reading (reading involves the translation of meaningful symbolic visual codes [orthographical representation] into pronounceable and distinguishable sounds of language [phonologic representation] so that a meaning [semantic representation] can be derived); (2) developmental psychology literature on when these representations develop and what might cause the development of a dysfunctional representational system (31); and (3) educational psychology literature on how the formation of functional representations can be aided or corrected when at risk for malfunctioning (32). One of the major theoretical frameworks for reading (30) is shown in Figure 5.2.3.2.

Here only brief commentaries relevant to these literatures are offered. Today, given the predominance of the phonology-based connectionist accounts of SRD, the behavioral manifestation of SRD is captured through a collection of correlated psychological traits. Although different researchers use different terms for specific traits, these can be loosely structured into groups aimed at capturing different types of information representation, for example: (1) performance on orthographic choice or homonym choice judgment tasks for quantifying parameters of orthographical representation; (2) phonemic awareness, phonologic decoding, and phonologic memory for quantifying phonologic representation; and (3) vocabulary and indices of comprehension at different levels of linguistic processing for quantifying semantic representation. Correspondingly, in studies of the etiology, development, and educational malleability of SRD, the quantification of the disorder is carried out through these various traits (or components of SRD). Thus, many studies attempt to subdivide SRD into its components and explore their etiologic bases, developmental trajectories, and susceptibility to pedagogical interventions separately as well as jointly.

DIFFERENTIAL DIAGNOSIS

The majority of students with LD are identified in middle and high school; this occurrence can be explained by the fact that early years of schooling might simply be insufficient for exposing and making evident a deficit in a particular academic domain. As mentioned, the core conceptual piece of the LD definition is that the deficit could have not been predicted reliably prior to the child's school entry because a child with LD demonstrates otherwise typical levels of cognitive functioning. Yet, there are known risk factors, the major cluster of which implicates atypicalities in early language development (33).

Previously, when the discrepancy criteria were applied, the diagnosis of LD was different from other forms of learning difficulties because of its stress on the specificity of the deficit (i.e., a discrepancy was expected not in *all* academic domains, but in a *specific* academic domain). The introduction of RTI-based approaches to diagnosis makes the question of differential diagnosis somewhat difficult to address. In fact, students with intellectual disability, emotional or behavior disorders, attention deficit hyperactivity disorder (ADHD), and other childhood and adolescent disorders might also exhibit low responsiveness to intervention. Yet their nonresponsiveness will occur for reasons very different from those experienced by students with LD. In other words, if RTI cannot differentiate LD from other diagnoses where learning difficulties are present but nonspecific, can RTI even be considered a classification/diagnostic instrument (34)?

Although this question has been raised, it has not yet been answered. The pre-2004 conceptualization of LD assumed that the texture of LD was in deficient (or different, atypical) psychological processing of information. In other words, the field was driven by the assumption that LD were likely to represent a dysfunction in one or more basic psychological processes (phonologic processing, sustained attention, different types of memory, executive functioning). These deficient processes, in turn, could slow down or inhibit mastery of a particular academic domain (reading or mathematics). Under this assumption, intensive academic instruction could improve performance in specific academic domains, but could not treat the disorder. Even if reading improves as a result of intervention, in this paradigm, the disorder might remanifest as a deficiency in a bordering domain (writing). In other words, although reading skills might be enhanced, the deficient psychological skills might impede some other academic domain of functioning.

Throughout the existence of the category of LD, there has been a consistent and strong demand from parents, researchers, and educators for the differentiation of these disorders from GLD. In its current iteration, RTI does not differentiate nonspecific and specific learning difficulties, because nonresponsiveness to intervention can occur with a variety of developmental disorders. In sum, because IDEA preserved the category of SLD, there is a new demand to differentiate SLD and

GLD by means of RTI and possibly other methods in the field.

One of these "other" methods has to do, of course, with psychological testing. Many researchers argue for the necessity of maintaining the role of psychoeducational and neuropsychologic tests on a variety of indicators, including IQ, in establishing an LD diagnosis (35). And this is exactly why the PSW model was introduced, although, at this point, there is not enough evidence to argue for its advantages.

COURSE AND PROGNOSIS

There is an accepted understanding in the field that LD are typically lifelong disorders, although their manifestations might and often do vary depending on the developmental stage and the demands of the environment (school, work, retirement) imposed on an individual at a particular time. This understanding assumes that LD do not manifest themselves exclusively in academic settings. In fact, the assumption here is that, although it might be successfully remediated during years of schooling, a particular LD might need further assistance and remediation in later years of functioning (as a part of the workforce). Although the literature on adults with LD is still somewhat limited, there is an accumulation of evidence that LD constitute a serious public health problem even after the schooling years. Such evidence is particularly rich in the field of studies of SRD.

LD are comorbid with a number of other disorders typically diagnosed in childhood or adolescence, especially attention deficit (36) and disruptive behavior disorders (37). LD also often co-occur with anxiety and depression (38). Correspondingly, individuals with LD are at higher risk for developing other mental health problems.

Yet the main drawback for individuals with LD has to do with their educational achievement. On average, only approximately 50% of students aged 14 and older diagnosed with LD graduate with regular high school diplomas. Correspondingly, the dropout rate among these students is very high (approximately 45%), and even higher for underrepresented minority students. The employment prospects of these students are also troubling—only about 60% of students aged 14 and older diagnosed with LD have paid jobs outside the home.

Thus, it is important to realize that the impact of LD is not limited to any one academic domain (reading or mathematics); these are lifetime disorders with wide-ranging consequences.

TREATMENT

Currently, there are no approved medical treatments for children with LD. There is a

consensus in the field that children with LD should be provided special education and related services upon establishing their eligibility and determining the necessity, content, duration, and desired outcomes of such education and services.

Yet, in much of the literature, many educators have expressed concern with the possible presence of faulty identification procedures in states and districts across the country, which has resulted in the possible abuse of the classification and service systems. In response to this concern, the 2004 reauthorization of IDEA makes reference to a set of prevention mechanisms intended to establish a better classification strategy for identifying children with LD. By law, schools need to implement systemic models of prevention that address (1) primary prevention: the provision of high-quality education for all children; (2) secondary prevention: targeted, scientifically based interventions for children who are not responding to primary prevention; and (3) tertiary prevention: the provision of intensive individualized services and interventions for those children who have not responded to high-quality instruction or subsequent intervention efforts. Per new regulations, it is assumed that this third group of children, those children who have failed to respond to age-, language-, and culture-appropriate, evidence-based, domain-specific instruction (in reading or mathematical cognition), can be identified as eligible for special education services. Of importance here is that these prevention mechanisms are also assumed to be used as diagnostic mechanisms (see the earlier discussion of RTI). This circular system of an outcome of intervention being also an entry point to diagnosis is currently creating significant turmoil in the literature and in practice.

In general, RTI approaches are conceived as a twofold simultaneous realization of high-quality, domain-specific instruction and continuous formative evaluation of students' performance and learning (39,40). In other words, RTI refers to ongoing assessment of students' response to evidence-based pedagogical interventions in particular academic domains. Thus, it is assumed that LD can be identified *only* when underachievement related to poor instruction is ruled out (6). Although present in a number of alternative forms, RTI includes eight central features and six common attributes. Among the central features linking all forms of RTI are: (1) high-quality classroom instruction; (2) research-based instruction; (3) classroom performance measures; (4) universal screening; (5) continuous progress monitoring; (6) research-based intervention; (7) progress monitoring during intervention; and (8) fidelity measures. Among common attributes of different RTI models, there are concepts of (1) multiple tiers; (2) transition from instruction for all to increasingly intense interventions; (3) implementation of differentiated curricula; (4) instruction delivered by staff other than the classroom teacher; (5) varied duration, time, and frequency of intervention; and (6) categorical or noncategorical placement decisions (41). Clearly, the concept of RTI is centered on the field's consensus of what high-quality, research-validated instruction is. It is important to note that, although there is

growing consensus with regard to critical elements for effective reading instruction, other domains of teaching for academic competencies are still not consensus driven.

There are numerous examples of RTI-based treatment of LD; two oft-cited ones are the Minneapolis Public School's Problem Solving Model, which has been in action since 1994 (42), and the Heartland (Iowa) Area Education Association's (AEA) Model, implemented in 1986 (43). The Minneapolis model is a three-tier intervention model where the referral to special education is made only after consecutive failures to benefit from instruction throughout all three tiers of pedagogical efforts. The Iowa model originally included four tiers, where the third tier was subdivided into two related steps, but then collapsed into one tier, similar to the Minneapolis model. Unfortunately, neither model has published empirical data on its effectiveness. Yet, years of implementations have resulted in appreciation from the communities they serve in a stable, relatively low special education population.

Currently, the concept of RTI is under careful examination by researchers supported by both the U.S. Department of Education and the National Institute of Child Health and Development. The future of RTI and its role in diagnosing and treating LD is dependent on answers to critical questions: (1) whether an RTI model can be implemented on a large scale; (2) how an RTI model can be used for LD eligibility determination; (3) whether RTI is an effective prevention system; and (4) whether RTI enhances LD determination and minimizes the number of false positives. As the field is getting ready for the reauthorization of the IDEA, answers to these questions become essential for how the federal law, in its next iteration, will define LD.

CONCLUSION

Currently, students with LD constitute about one-third of all students served under IDEA. Effective identification of such students and their efficacious and efficient remediation are crucial steps to addressing their individual educational needs and providing them with adequate and equitable life opportunities.

Given changes in IDEA 2004, it is of no surprise that RTI is central to current discourse on LD. RTI is central to professional discussions of educators, diagnosticians, and policymakers because of its promise to alleviate many long-standing concerns with the AADC predominant in the field of LD for the last 30 years. At this point, however, RTI has yet to deliver on its promise and PSW has yet to be thoroughly researched. The next year or two, as the reauthorization of IDEA gets underway, will be key, once again, for revisiting the criteria for the identification of LD.

---

[1]The previous version of this law, Public Law 105–17 (signed in 1997), was called Individuals with Disabilities Education Act, IDEA.

[2]It is important to note that RTI might appear counterintuitive at first: How can a disorder be defined through treatment if treatment is prescribed for a particular disorder? This "circularity" of RTI, however, is only superficial. An implicit assumption behind RTI is that teaching is inadequate and that is why schools "produce" such a high level of LD. A closer analogy would not be with treatment, but with prevention with vitamins; if vitamins were delivered properly, then many deficiencies could be avoided. Thus, if all children get preventive extensive instruction, the frequencies of LD will diminish.

CHAPTER 5.2.4 ■ DISORDERS OF COMMUNICATION

ELIZABETH SCHOEN SIMMONS AND RHEA PAUL

Language, a unique and characteristic capacity of the human mind, is also one of its most vulnerable faculties. Virtually any disruption in cognitive function, particularly during early development, can affect language acquisition. For this reason, disorders of language development typically accompany a variety of conditions but they can occur in relative isolation as well. It is also true that language is just one form of communication. The term *communication* refers to all forms of sending and receiving messages, not only with spoken language, but in other ways, such as with gestures or facial expressions. Within the realm of communication, *language* represents one specific type, which involves generating a potentially infinite set of never-before conveyed messages through the combination of symbols in rule-governed ways that allow the formation of sentences to express meaning to others. Language, like communication, can be conveyed in a variety of forms including written expression or manual signs seen in American Sign Language (ASL). *Speech,* on the other hand, is a particular modality of language, its expression through the use of sounds produced by oral movements (Figure 5.2.4.1).

DEFINITIONS

The American Speech-Language-Hearing Association (ASHA) has defined *language disorder* as an impairment in "comprehension and/or use of a spoken, written, and/or other symbol system. The disorder may involve (1) the form of language (phonologic, morphologic, and syntactic systems), (2) the content of language (semantic system), and/or (3) the function of language in communication (pragmatic system), in any combination" (1, p. 40). This definition means that a language disorder can be seen as a disruption in any aspect of verbal communication, whether oral or written. It is important to note that this impairment is not necessarily defined only in relation to cognitive level or mental age. Current practice (2) dictates that any child whose language is inadequate for communication can be diagnosed as having a language disorder, even a child who is intellectually disabled with a mental age commensurate with his current level of language function.
FIGURE 5.2.4.1. Relationship among speech, language, and communication and their components.

Speech disorders are more limited difficulties that refer to problems with the production of spoken language, although comprehension may be intact. Speech disorders can affect the fluency of speech (e.g., stuttering), the perceived quality of production (e.g., voice disorders), or the pronunciation of particular sounds (e.g., articulation disorders).

EPIDEMIOLOGY

Accurate estimates of prevalence of specific language disorders are difficult to come by because of methodologic differences across studies (e.g., in the subclassifications and definitions; in the cutoffs and inclusionary criteria; and in the age, sex, and other characteristics of the children sampled). However, delays in language development are the most common presenting symptom in preschool children (3). The most recent NIH estimates prevalence for speech/language disorders at 11% for children 3 to 5 years old and 9% for those 6 to 8 years old (4,5). The prevalence estimate is 8% for

boys and 6% for girls (6).

In post-primary school age, the prevalence of primary language disorders is thought to be between 4% and 7% (7), although there is overlap with related disorders, because some preschoolers with language disorders “grow into” school-age learning disabilities and dyslexia (8). Specific language disorders and learning disabilities combined are some of the most prevalent disorders of school-age children (9).

ETIOLOGY

Again, etiologic discussions are complicated by the fact that language disorders can exist as circumscribed syndromes, but also accompany a range of other developmental disorders. For this reason, we will restrict our discussion of etiology to specific language impairment (SLI). Neurobiologic factors are clearly implicated in the disorder as evidenced by genetic factors in SLI (10), including higher concordance in monozygotic than dizygotic twins (11) and higher than normal risk in family members for language and learning problems if a child has SLI (12–14). Additionally, there is emerging evidence that has identified candidate genes that may be responsible for behavioral phenotypes commonly observed in SLI (15). The results of these linkage investigations suggest that single nucleotide polymorphisms (SNPs) may be responsible for language ability and disability. While specific genes, such as FOXP2 and CNTNAP2 (16,17) have been identified as candidate genes in SLI in some studies, these findings have yet to be replicated. Finally, it is important to note that genes associated with SLI have also been associated with other psychiatric conditions including autism spectrum disorder (ASD) and attention-deficit hyperactivity disorder (18).

Just how specific are specific language disorders? Children with SLI are at greatly increased risk for attention and activity problems (19,20). Other “soft” neurologic signs are also frequently present in children with SLI (21). A variety of nonverbal cognitive skills have also been implicated in SLI (22,23). These findings have led to the hypothesis that children with SLI may have not just a language problem, but a general representational deficit, affecting a variety of kinds of symbolic functioning (24), deficits in aspects of cognition, primarily memory (25,26).

Imaging studies have demonstrated some differences in brain function between children with and without specific language disorders. Typically, individuals have asymmetrical brains; language structures (such as the planum temporale) tend to be bigger in the left hemisphere. However, children with SLI have generally smaller and more symmetrical brain hemispheres (27). Studies of adults with language difficulties have revealed that they were more likely than individuals with no history of language impairment to have an extra sulcus in Broca’s area, in either brain

hemisphere (28). Studies that employ functional imaging techniques have revealed less activation within the gray matter during auditory tasks (29). A recent review of neuroimaging studies in language disorders (30) reports both functional and structural anomalies associated with language disorders, primarily in the finding of greater activity and volume relative to controls. Cortical and subcortical atypicalities in the language network have been reported, with little consistency across studies, except in the superior temporal gyri. It is important to realize that no single patten of brain architecture has been shown consistently in all individuals with language impairment. Instead, these structural differences appear to act as risk factors for language difficulty.

In summary, there is evidence for a genetic component in specific speech and language disorder. However, there are few agreed upon biologic markers of SLI. Although neurobiologic methods have demonstrated differences in the neural structure and auditory functioning of children with SLI, reliable clinical markers have not yet emerged.

SYNDROMES INVOLVING COMMUNICATION DISORDERS

Intellectual Disability

Limitation in communicative skill is often one of the first signs of intellectual disability (ID). Children with ID are often first recognized because of their failure to begin talking at the normal time. The sequence of language acquisition in children with this disability follows, in general, the sequence of normal acquisition, although some differences can be identified (31). Many children with ID show communicative skills that are commensurate with their developmental level, but more than half have language skills that are less than what would be expected for mental age (32). Phonologic errors are prevalent in children with ID. These children make similar errors to those seen in normal development, but errors are more frequent (33). Pragmatic skills are usually similar to those seen in children at similar developmental levels (34). The two most prevalent syndromes of ID, Down syndrome (DS) and fragile X syndrome, are both very frequently associated with various problems in language development (35,36). About a third of children with fragile X also exhibit symptoms of autism (37). Social communication skills in many children with DS tend to be relatively preserved, although 8% to 14% of this population, too, is reported to show symptoms of autism (38). Other syndromes, such as Prader–Willi, also exhibit language deficits (31). Even in Williams syndrome, in which it was previously thought that language was an unexpected strength, research has shown that language is preserved relative to nonverbal skills, but does not typically exceed developmental level (39).

Hearing Impairment

Children with impaired hearing are vulnerable to language disorders because of their lack of access to the linguistic information from the auditory signal. Still, children with hearing impairments (HIs) vary greatly in their oral language ability. With hearing aids, children can be moved from greater to lesser levels of severity of hearing loss. Cochlear implants and tactile aids are also used to provide auditory information to children who would otherwise be considered deaf (40). In recent years, cochlear implants are being used more routinely at earlier ages to facilitate language development in children born with severe hearing loses, and research (41–43) suggests this results in very good outcomes in terms of speech and understanding language.

Use of language for communication is not a major problem area for children with HI. Rather, most of their difficulties lie in acquiring the conventional verbal forms of communication. Reading and writing present particular problems, primarily because of the language basis necessary for acquiring these skills. Average reading comprehension level for adolescents with HI without cochlear implants is third to fourth grade (44–46). Language and reading outcomes for children who receive cochlear implants are generally higher (42,47).

Some children with HI, especially those who come from families in which one or more parent is deaf, can be taught to bypass the auditory channel through the use of manual Sign language. Using this method, children can develop fluency and eloquence in sign that would never be available to them through the modality of speech. There is controversy within the community of the hearing impaired as to the role of Sign language versus oral language instruction for children with severe hearing loss. In general, nonimplanted deaf children taught sign develop higher-level language skills than those taught speech, although their communication may be limited to those in the deaf community who use sign as their mode of communication.

Psychiatric Disorders

There is a very high comorbidity between sociobehavioral and communicative disorders (47,48). Benner et al. (50) found, in a meta-analysis, that over 70% of children diagnosed with emotional–behavioral disorders (EBD) had clinically significant language deficits. The deficits were broad-based and included expressive, receptive, and pragmatic aspects of language. This finding has been confirmed in studies of bilingual children as well (51). In addition, over 50% of children diagnosed with language deficits also had diagnosable EBD. Further, the number of children who have both communicative and behavioral–socioemotional disorders increases as children with language disorders get older (52). It may be impossible to know the source of this connection. Some writers (53) hold that a communication

problem leads to frustration, creating behavioral or emotional disorders. It may, alternatively, be the case that a behavioral–socioemotional problem leads to decreased motivation to communicate or an inability to "tune in" to learn the rules of communication or use language for self- and other-regulation (54) or perhaps diagnostic overlap between disorders (55). Studies of genetics may help us understand diagnostic comorbidity, especially when two disorders arise from similar genetic underpinnings (56). Whatever the answer to these questions, children with language problems are vulnerable to socioemotional difficulties, and children with psychiatric diagnoses show a higher than normal prevalence of language disorders.

Selective Mutism

The psychiatric problems that most commonly co-occur with language disorders include attention-deficit hyperactivity disorders, conduct disorders, and anxiety disorders. One particular form of anxiety disorder, selective mutism, has the most obvious communicative concomitants. DSM-5 (57) defines selective mutism as a persistent refusal to talk in one or more major social situations, including school, despite the ability to comprehend and use spoken language (58). High levels of social anxiety are often also present (58). The problem has been recognized for at least a century (60) and is relatively rare, with prevalence rates of 0.3 to 0.8 per 1,000 (57). Selective mutism is most often seen in school settings, where the child refuses to speak despite being verbal at home. Cultural and linguistic differences (CLDs) can exacerbate the problem, especially when the child has limited English proficiency (LEP) and feels uncomfortable using the language of the classroom (61). The condition shows a 2:1 ratio in favor of girls (62). In spite of the fact that the diagnostic criteria require the child to have the ability to use language in some situations, a high incidence of speech and language difficulties has been reported in this population. Seventy-five percent of children with selective mutism have been found to have articulation disorders and expressive language problems; 60% show significant deficits in receptive language (63,64). Speech-language pathologists often work in collaboration with mental health professionals to address the needs of the selectively mute child. Recent reviews (65,66) report evidence that behavioral intervention was the most effective approach. These techniques include contingency management (positive reinforcement of verbalizations and nonreinforcement for nonverbal responses), stimulus fading (gradually extending the number of people with whom and environments wherein verbalization is rewarded), shaping (rewarding gradual approximations to speech, such as mouthing and whispering), and response cost procedures (losing money or tokens for not speaking) (67,68). Multimodal interventions that combine behavioral or cognitive-behavioral approaches with psychodynamic approaches, family involvement, and other therapies such as music or dance also showed some degree of efficacy (69). Pharmacologic intervention produced no recovery when used alone, but use of selective serotonin

reuptake inhibitors (SSRIs) appears to have an ancillary role in the treatment of selective mutism when combined with other approaches (70). Music therapy also showed emerging evidence of efficacy (71).

Autism Spectrum Disorder

The psychiatric disorder most consistently associated with communication deficits is ASD. Communication problems—including severe delays in language, inability to communicate nonverbally, inability to sustain conversation, stereotyped and repetitive use of idiosyncratic language, and abnormal ability to use language for social communication—are included in the diagnostic criteria for ASD (72). Virtually all children with autism have some form of communication disorder that presents as part of their syndrome. What differentiates autism from a more circumscribed language disorder is the global nature of the child's communication problem. Not only is language affected, but also the ability and motivation to send messages by any means, either verbal or nonverbal, is severely impaired.

From early in development, children with ASD show differences in intentional communication. Major differences seen in 1 year olds later diagnosed with ASD include a lack of joint attentional behavior and an abnormal response to human faces and voices. These babies use gestures to show and point less often than language-matched controls, although they do use gestures to request, protest, and regulate others' behavior (73). In general, they do not communicate in order to share focus as normal infants do, but only to express wants and needs (74). Some children with ASD do not develop speech, approximately 30% depending on study; although the proportion who do not is declining as earlier identification and intervention is being implemented (75–77). When speech is absent, it is not spontaneously replaced by communicative gestures, as it is in children with HI, for example. Furthermore, children with ASD may develop maladaptive means for expressing requests and protests. They may begin head-banging, for example, to express rejection of an activity. In children with ASD who do develop speech, some expansion of communicative intentions occurs, along with an elaboration of more socially acceptable means of communicating (78).

Children with ASD who do talk begin speaking late and develop speech at a significantly slower rate than other children (78). About 25% of children with ASD appear to acquire a few words by 12 or 18 months, and then lose them or fail to acquire more (79). When children with ASD begin talking, aspects of language form, including phonology, syntax, and morphology, are relatively spared. These children generally show skills in language form that are at or close to those of mental-age mates (78), although a subgroup of children with ASD show deficits in language form that are similar to those of children with SLI (74). Vocabulary skills also are usually on par with developmental level. Meaning and pragmatic aspects are disproportionately impaired, though (80). For individuals with ASD who develop

spoken language, verbal output may lack spontaneity and remain somewhat sparse. They generally have trouble adapting what they say to the needs and status of the listener, distinguishing given from new information, following politeness rules, making relevant comments, maintaining topics outside their own obsessive interests, and giving listeners their fair share of conversational turns (78).

A classic characteristic of autistic language is *echolalia*, either immediate or delayed (81,82). Although echolalia was long thought to be a dysfunctional language behavior, investigators such as Fay (83) and Prizant and Duchan (84) have shown that children with ASD often use echolalia for communicative purposes. Echolalia in ASD is selective, as it is in normal development (85). Children with ASD who echo tend to do so when they do not understand what has been said to them or when they lack the language skills to generate an original reply (86). Although echolalia is a "classic" symptom of autistic disorders, not all verbal children with ASD use it. Fay (87) estimated that it appears, at least briefly, in about 75% of autistic children who speak. Also, echolalia is used by children with other syndromes, such as blindness and fragile X syndrome. As language skill in children with ASD improves, echolalia decreases, as it does in typical development.

Paralinguistic aspects of communication also are affected in verbal children with ASD. Intonation is often monotonous and machinelike, and stress, vocal quality, rate, rhythm, prosody, and loudness deviances also have been reported for approximately half of higher-functioning speakers with ASD (88,89). The reasons for these paralinguistic differences are not known. Paralinguistic aspects of communication do, though, carry some of the pragmatic and emotional information in the message. The deficits in affective development seen in children with ASD may, then, form some part of the explanation.

Social (Pragmatic) Communication Disorder

This new diagnostic classification is identified in DSM-5 (57). Those diagnosed with this disorder demonstrate a primary deficit in the social use of language, specifically pragmatics, but fail to display the restricted and repetitive behaviors (RRBs) seen in ASDs. Children who are diagnosed with social communication disorder (SCD) may demonstrate difficulties initiating and maintaining conversation, adapting their communication style to accommodate various listeners or show problems in comprehending higher-level language needed for social exchanges (e.g., inferences). Children with SCD have intact formal language skills; that is, vocabulary, morphology, and syntax, are roughly in the average range; they show no history of RRBs (90). This new diagnostic classification may be useful in better quantifying the social language impairments observed in other psychiatric conditions (91), but there is limited evidence of its diagnostic validity (92).

ACQUIRED DISORDERS OF COMMUNICATIVE FUNCTION

ACQUIRED DISORDERS OF COMMUNICATIVE FUNCTION

Language disorders acquired during the developmental period can be broadly categorized as those related to focal lesions (93,94); and those in which more widespread damage is sustained, usually in association with seizure disorders (95,96) or traumatic brain injury. These disorders and their remediation are described in Paul and Norbury (97).

Disorders with Environmental Components

Fetal Alcohol Syndrome

Fetal alcohol syndrome (FAS) is the most impairing form of fetal alcohol spectrum disorder, which is a continuum of impairments as a result of exposure to alcohol in utero (98). Communication disabilities are almost universal in those with FAS (99) and are related to the level of intellectual impairment. These disorders include delayed development, poor receptive vocabulary and comprehension, and pragmatic difficulties. Perseveration and echolalia are often present in children with more severe impairments (100).

Drug Exposure

Although prenatal drug exposure is a developmental risk, fewer than half of children exposed to drugs prenatally experience low birth weight, prematurity, intrauterine growth retardation, or small head circumference (100,101). Sparks (101) reported that drug-exposed newborns are often irritable and stiff and show arousal and attention problems, but these traits do not appear to last past the first year. In general, cognition is not impaired, except when reduced head size is present. Still, catch-up head growth is a marker of good prognosis for long-term development (100). Several studies (102–105) have found that children with a history of cocaine exposure show delays in language acquisition, particularly in the area of expressive language, with exposure to higher-doses prenatally resulting in higher levels of impairment. However, these studies also find that effects are modified by an enriched environment; children placed in foster or adoptive homes show higher levels of communicative skill than those who remain with biologic mothers.

Child Abuse and Neglect

Children with communicative and other developmental disorders are, as Knutson and Sullivan (106) pointed out, more likely than normally developing children to experience maltreatment. Similar findings were reported in a meta-analysis of 17 studies examining the prevalence of abuse and neglect in children with developmental disorders, including communication impairments (107). Fox et al.

(108) suggested that a child with a communication disorder might be less satisfying for a parent to care for and provide less rewarding interactions. These difficulties might predispose a child to abuse.

Maltreatment itself also constitutes a risk for language disorder. Culp et al. (109) argued that language development is particularly vulnerable in the maltreatment situation, because of the disruption in social interaction it entails. Preschool children who were maltreated are more likely to exhibit language delay compared to other developmental issues, such as motor or cognitive impairments (110). Coster et al. (111) showed that maltreated toddlers used shorter sentences and more limited vocabularies during play with their mothers than peers from nonabusing homes. Both Allen and Oliver (112) and Eigsti and Cicchetti (113) found that preschoolers with a history of maltreatment had significantly lower language scores than peers of similar socioeconomic level, with impairments in both vocabulary and sentence production. Lynch and Roberts (114) showed that these children scored significantly lower on verbal IQ relative to nonverbal scores. Fox et al. (108) found that maltreated children had receptive language deficits, with neglected children suffering greater lags than those shown by children who were abused. Moreover, there are cascading effects on development for children who have been maltreated, including altered cognitive functioning in adulthood and increased risk of psychiatric disorders (115).

SPECIFIC SPEECH AND LANGUAGE DISORDERS

Communication disorders can be associated with a variety of conditions but they can also occur in relative isolation. These more specific disorders of speech and language development can still have broad effects on a child's ability to succeed in social and academic pursuits because communication is so central to human interaction and the development of the intellect. We will examine the types of specific speech and language disorders discussed in the DSM-5 (57): Childhood-onset fluency disorder (stuttering), speech sound disorder, and language disorder.

Specific Speech Disorders

Stuttering

This syndrome involves abnormal and persistent dysfluencies that result in deviations in the continuity, smoothness, rhythm, and/or effort with which phonologic, lexical, morphologic, and/or syntactic language units are spoken (116); these are often accompanied by affective and behavioral reactions. Several types of speech dysfluencies also may be involved, including blocking of sounds, hesitations, and tense pauses. Incidence of childhood stuttering is highest between a child's second and fourth birthdays, ultimately affecting 4% to 5% of the population. Although many

children go through periods of dysfluency during the developmental period, these "normal dysfluencies" tend to occur in the larger linguistic units (word, phrases, and sentences). For children who tend to persist in stuttering over time, dysfluencies are more likely to occur in repetitions of syllables ("vi-vi-vi-vi-video") and sounds ("g-g-g-g-ot"). Other "red flags" for persistent stuttering include sound prolongations ("WWWWWait!"), silent blocks in which the child attempts to speak but no sound comes out, and visible struggle behaviors during speech, such as blinks or grimaces (8). If dysfluencies continue to be relatively effortless, there is a good chance of recovery. In addition, Yairi et al. (117) reported that children who recover from stuttering begin to show reductions in their number of dysfluencies within the first year, whereas those who persist in stuttering are relatively stable in their rate of dysfluency.

When recovery occurs, it usually does so by adolescence, often around the time of puberty. For individuals with chronic stuttering, the severity of the disturbance varies from situation to situation and is more severe when there is pressure to communicate. Stress or anxiety has been shown to exacerbate stuttering, but is not thought to play a role in the etiology; however, in a study of adolescents, those who stutter have a higher rates of social and trait anxiety compared to nonstuttering controls (118). Reducing stress during speaking can reduce stuttering episodes (119), but general treatments for anxiety, including the use of tranquilizing medication, have not been found to be effective for the stuttering itself (120). In general, speech therapy is used both to shape fluent speech and help the patient to stutter with less tension, avoidance, and interruption of the flow of communication (121,122). Psychotherapy alone has not been shown to be an effective treatment for stuttering, but counseling is often helpful for overcoming the secondary effects of stuttering on self-concept, thoughts, and feelings (123). Today, stuttering is believed by most researchers to have a complex multiplicity of causes that include biologic vulnerability, environmental demands and expectations, and temperamental characteristics of the speaker (124).

Speech Sound Disorders

These difficulties with speech articulation are characterized by impaired production of developmentally expected speech sounds. To diagnose a speech sound disorder, it is necessary to ascertain that the problem is not attributable to deficits or abnormalities in intelligence, hearing, or the structure and physiology of the speech mechanism. So a speech sound disorder is one in which, although there is no organic reason for the disability, the child's speech is marked by developmentally inappropriate misarticulations, including distortions of sounds (e.g., /s/ is produced with a lisp), omissions of sounds (e.g., *up* is pronounced "uh," *play* is pronounced "pay"), and incorrect substitutions of one sound for another (e.g., *cat* is pronounced "dat"). Many of these misarticulations represent processes that are typical in the

speech of young typical children (e.g., deletions of final consonants, simplifications of consonant clusters), but in speech sound disorders more of them are used, they are used more often, and their use persists beyond the normal developmental period. There may also be idiosyncratic preferences for and/or avoidances of certain sounds or sound simplification processes (125–127), and/or reversals or misordering of sounds in words (128). Speech sound disorders are the most prevalent type of communication problem. Edwards (129) reported that 80% of speech clinic referrals were for articulation disorder. Six percent of school-age children have phonologic disorders. The prevalence is higher for preschoolers, with estimates ranging from 10% to 15% (4).

Speech sound disorders can, of course, occur with many of the syndromes discussed in the preceding. They can also occur in isolation, and are commonly associated with specific language disorders. Shriberg and Kwiatkowski (130) found that over 50% of children with speech sound disorders have delays in expressive language, and 10% to 40% have delays in language comprehension. Shriberg and Kwiatkowski (130) reported that a significant minority of these children, with either speech-only or speech/language delays as preschoolers, required continuing special services throughout their elementary school years.

Childhood Apraxia of Speech

A subset of children with severe, persistent speech disorders accompanied by certain language and behavioral features are sometimes said to have a *childhood apraxia of speech (CAS)* (131–134). Although there is not a well-established set of diagnostic criteria, characteristics most commonly attributed to this syndrome (131–136) include:

- Limited repertoires of speech sounds
- Predominant use of simple syllable shapes
- Frequent sound omission errors
- Slow rate of speech
- Difficulties with imitating sounds and speech
- Production in single words is better than in connected speech
- Stress and pausing may be unusually equal across words, with loss of normal intonation quality

Davis (137) and Shriberg (138) discussed some of the controversies surrounding this disorder. First, some degree of connected speech is necessary to make the diagnosis. Children who are not speaking at all cannot technically be diagnosed with CAS for this reason, although nonverbal children do often receive this diagnosis erroneously. Second, CAS was originally defined as an analog to an adult-acquired neurologic disorder: apraxia of speech, or a neurologically based difficulty in

programming speech movements, thought to take place at a prearticulatory motor planning level. Intensive investigation, however, has not been able to document any consistent neuropathology in children who show this speech pattern, even with sophisticated new techniques. Partly as a result of this failure to identify a neurologic lesion similar to the one that causes apraxia in adults, and the fact that the behavioral symptomatology associated with CAS overlaps extensively with other conditions, such as developmental phonologic disorders and expressive language delays, accurate and reliable diagnosis is difficult. In general, it is best to be conservative about the diagnosis of CAS, and to reserve it for children who have demonstrated some connected speech production but fail to make progress in articulation after an intensive trial of traditional speech therapy.

Specific Language Impairment

Some kinds of language disorders have no known concomitants. These disorders have been traditionally defined by exclusion, that is, by the absence of the other factors—ID, sensory disorders, neurologic damage, emotional problems, or environmental deprivation.

Rescorla and Lee (139) have argued on the basis of recent evidence regarding the development of very young children with delayed speech (140,141) that it is not appropriate to make the diagnosis of SLI until age 4. Research suggests that younger children with delayed language have a good chance of "outgrowing" their slow start, although their language functioning may seem very similar to children with SLI at earlier ages (142) and they frequently retain subtle weaknesses when compared to matched social-economic peers (143–147).

Children with SLI are frequently late to begin talking. When they do begin to talk, they add new words slowly. They may continue to use single word or telegraphic utterances into their third year. In general, communication patterns of children with SLI are similar to those of younger children at comparable levels of language development. While this pattern holds true when looking at one specific feature of development at a time, Leonard (148) pointed out that children may be 1 year below age level in one set of features, 1½ years below in another, 6 months below in a third, and so on. The result will be that the overall profile of language skills in a child with SLI may not resemble that of a child with normal language function at any point in development. This does not mean that language development is deviant, but rather that it is in some ways asynchronous (31).

Early lexical usage in children with SLI is very much like that of normally developing children at similar language levels but is acquired at a slower pace. Vocabulary sizes of normally developing 2 year olds are more than 200 words, whereas those of children with SLI are in the range of 20 words (141–151). Moreover, children with SLI talk and communicate less often than same-age peers (139). While these children acquire sounds and make speech errors that are similar

to those of peers, their repertoires of consonant sounds are smaller, and they take longer to acquire basic word forms (152–155).

Although vocabulary deficits are the first sign of language delay, these typically resolve by ages 3 to 4 (150,151). Use of early semantic relations appears similar to that of language-matched peers (148). Vocabulary in school-aged children with SLI lags behind that of peers (156,157), perhaps because of reduced experience through reading (which is often problematic for these children) (158).

Delays in syntax emerge between 18 to 24 months of age in children with SLI as evidenced by a failure to spontaneously (141,149,159,160). Follow-up studies indicate that these children continue to lag behind in syntactic development through the preschool period (142,161). They appear to acquire grammatical structures in roughly the same order as normally speaking children do, although they make more errors for longer periods and use higher rates of ungrammatical sentences (139,160). Some recent electrophysiologic evidence suggests reduced sensitivity to cues within sentences to the grammar of subject–verb agreement (162), although there are several alternative theories to explain this widespread observation in English-speaking children with SLI.

Pragmatic skills are generally better than skills in language form, and this is one of the characteristics that differentiates SLI from ASD (163). While children with SLI have been reported to be less interactive than age-matched peers, they are often similar to younger language-matched children (139), and pragmatic deficits seen are usually in the mild range (30). Still, Marton et al. (164) report finding significant deficits in social knowledge in children with SLI and others have reported subthreshold autism symptomatology (165).

For children with chronic mild to moderate language disorders, problems in the school years tend to narrow in their focus and to be concentrated in subtle difficulties of language organization and efficiency, rather than frank errors (143,144). Word retrieval or “word finding” difficulties, are common. A child with SLI may substitute an incorrect word of related meaning (e.g., “table”); or use functional descriptors (e.g., “thing to sit on”), vague or general terms (e.g., “thing”). Storytelling and discourse problems often persist and affect both oral and written modes of expression (149,166). There may be tangential or inappropriate responses to questions, a limited range of communicative functions (e.g., requests, imperatives, questions) expressed, difficulty maintaining and/or changing topics, and difficulty initiating interactions (167). Academic problems tend to involve primarily reading and writing. Despite their persistent problems, however, most of these children do finish high school, some go on to college, and most live independent lives (144,145,168).

DIFFERENTIAL DIAGNOSIS

When seeing children suspected of having specific speech and language disorders, the main diagnostic task is to rule out other syndromes with which speech and language problems are frequently associated. These syndromes include the ones discussed in the early section of this chapter; that is, deafness or significant hearing loss, ID, ASD, psychiatric disorder, organically based communication disorders (e.g., cleft palate, apraxia, cerebral palsy, or childhood-acquired aphasia), or a disorder associated with maternal substance abuse or maltreatment.

The absence of significant HI must be established by audiometric testing by a certified audiologist. Because subtle deficits in hearing can affect language acquisition, it is important to get complete and accurate results in order to assure that hearing deficits do not play a role in the disorder. Although chronic middle ear pathology is sometimes associated with speech and language problems, research (169,170), suggests that chronic otitis media alone does not significantly increase the risk of language disorder in otherwise normal children.

ID must be diagnosed by means of an individually administered, standardized test of intelligence, as well as by a standardized measure of adaptive behavior. For children suspected of language disorders, it is necessary to use nonverbal intelligence tests to assess intellectual ability, so as not to penalize the child for the language deficit and to obtain an estimate of intelligence unbiased by language performance. It should be noted, though, that even in nonverbal measures, children with SLI tend to score lower (though within the normal range) than average (171). It is not necessary to show that a child has language skills that are lower than expected for IQ in order for the child to receive communication services through the public schools. According to Individuals with Disabilities Education Act (IDEA) Part B, Children with ID can qualify for these school-based services if their communication skills significantly impact their access to social and academic opportunities.

Organic disorders that can affect the speech mechanism, such as dyspraxia, dysarthria, and motor deficits associated with cerebral palsy, can be ruled out by physical and functional assessment of the speech mechanism. A speech-language pathologist (SLP) typically examines the morphology, symmetry, and alignment of the facial features. The functional integrity of the larynx, lips, tongue, and velopharyngeal structures, as well as the respiratory support for speech are also assessed. The quality of oral volitional movements also may be examined if an apraxia is suspected. If physical limitations to speech production are identified, an alternative system of communication—such as a picture board or electronic communicative device—may be indicated (172,173). However, it is important to note that difficulties in imitation and cognition can affect a child’s ability to participate in these assessments. Finding typical speech motor performance can rule out neuromotor involvement, but a finding of poor performance is more difficult to interpret, especially in developmentally young children.

Psychiatric/behavioral assessment can rule out ASD and other psychiatric

disorders. Features associated with ASD include lack of (nonverbal) social interactions, absence of imaginative activity, stereotypic behaviors, self-injurious behaviors, odd responses to sensory input, and mood abnormalities. Formal measures, such as the Autism Diagnostic Interview (ADI; 174) and the Autism Diagnostic Observation Schedule (ADOS; 175), as well as checklists such as the Childhood Autism Rating Scale (CARS; 176) can assist in differential diagnosis.

The differential diagnosis among stuttering, speech sound disorder, language disorder, and selective mutism requires comprehensive speech/language testing. To diagnose stuttering, a clinician should ascertain, by means of standardized testing, that other language skills are age appropriate. If dysfluency coexists with other speech and language disorders, it may be appropriate to delay making a diagnosis of stuttering until some of the other problems resolve, then reevaluate to determine whether the dysfluency has persisted. For young children, too, dysfluency may be transient. If the preschool dysfluent child is not showing any signs of struggle or self-consciousness about speech, it may be wise to "watch and see," and re-evaluate the child in 6 months before initiating a course of speech therapy.

Speech sound disorders are diagnosed by means of standardized testing of sound production, usually using procedures that ask children to name pictures or objects and transcribing the child's rendition of the target word for comparison with adult production standards. Because these disorders typically coexist with other language disorders, it is acceptable to confer a concurrent diagnosis of speech sound disorder even if other language disorders are present. However, it is necessary to rule out HI, ID, and speech mechanism limitations before diagnosing a specific speech disorder.

To diagnose a specific a language disorder, it is necessary to demonstrate—by means of individually administered, standardized tests—that expressive and/or receptive language skills are below the expected level of function. Again, because speech sound disorders so frequently coexist with language deficits, especially expressive language impairments, both conditions can be diagnosed concurrently.

TREATMENT OF SPEECH AND LANGUAGE DISORDERS

It is important to make a careful differential diagnosis of any communication disorder in order to decide whether the problem is specific to speech and language or is part of a larger syndrome. In the case of communication disorders associated with syndromes such as HI, ID, and autism, treatment must address all aspects of the child's problem, not just those of speech and language.

The treatment of choice for all the disorders discussed here, except selective mutism, is individual or small group therapy administered by a certified SLP. Because associated educational and/or psychiatric problems are common with these disorders, educational tutoring, social skills training, and/or psychiatric intervention also may be indicated, even if the disorder is specific to communication.

Methods of intervention are essentially behavioral and educational. Some clinicians use strict operant procedures, whereas others favor more child-centered approaches such as indirect language stimulation, which involves a rich communicative environment with opportunities for incidental learning. Many SLPs take a middle ground between these extremes, using structured play opportunities and focused stimulation to provide examples of desired forms and elicit language targets. Although all these methods have been shown to be effective in small studies (97,177,178), much more research is needed on the efficacy and effectiveness of particular approaches to intervention and variables that can be used to best match the method to the child.

Caution should be exerted when treatments make claims of dramatic improvement, particularly when the improvement is claimed for a broad range of disorders. Clinicians who work with families of children with communication disorders need to maintain a healthy skepticism regarding these programs that make extravagant claims. Any intervention, whether familiar or innovative, must be shown to meet the particular needs of the patient receiving it. Communicative interventions need to be evaluated with the same kind of rigor that would be used to evaluate the efficacy of a medical or surgical treatment. Although double-blind, placebo-controlled, randomized assignment trials are difficult to design for behavioral interventions, clinicians must strive to achieve some degree of objective evaluation before deciding that a treatment is appropriate for a given individual.

ACKNOWLEDGMENTS

Preparation of this chapter was supported by Research Grant P01-03008 funded by the National Institute of Mental Health (NIMH); by the Studies to Advance Autism Research and Treatment (STAART) Center grant U54 MH66494 funded by the National Institute on Deafness and Other Communication Disorders (NIDCD), the National Institute of Environmental Health Sciences (NIEHS), the National Institute of Child Health and Human Development (NICHD), the National Institute of Neurological Disorders and Stroke (NINDS); by a MidCareer Development grant to Dr. Paul, K24 HD045576 funded by NIDCD; the National Alliance for Autism Research; as well as the Integrative Graduate Education and Research Traineeship Program (IGERT) Grant 1144399 funded by the National Science Foundation (NSF).

5.3 PSYCHOTIC DISORDERS

CHAPTER 5.3 ■ CHILDHOOD-ONSET SCHIZOPHRENIA AND OTHER EARLY-ONSET PSYCHOTIC DISORDERS

ANNA E. ORDÓÑEZ AND NITIN GOGTAY

BACKGROUND

Psychotic disorders are rare in children although transient psychotic experiences are more common in otherwise healthy children than generally recognized (1–3). As is often the case with other very early-onset illnesses, psychotic disorders in children are usually more severe than their adult counterparts (4), and the disruption of cognitive and social development as well as the burden to the family can be devastating. Systematic research in this area was initially limited by diagnostic uncertainty and the general lack of knowledge about the psychotic processes in children (5).

History of Childhood-Onset Psychoses

Although the existence of childhood schizophrenia was recognized early in the twentieth century (6), the term psychosis was used so broadly in children that a spectrum of behavioral disorders and autism were grouped together under the category of childhood schizophrenia (7). The landmark studies of Kolvin (8) first established the clinical distinction between autism and other psychotic disorders of childhood. However, even today high rates of initial misdiagnosis remain due to symptom overlap, particularly for mood disorders (9–11), and the presence of transient hallucinations and delusions in nonpsychotic pediatric patients (3,12,13). Overall, hallucinations and delusions appear more prevalent in children and early adolescents than in older adolescents (14,15), with a recent meta-analysis of population studies reporting median prevalence of psychotic symptoms among children ages 9 to 12 years of 17%, and among adolescents 13 to 18 years of 7.5%.

Nonetheless, while the occurrence of psychotic-like experiences in many children and early adolescents will have short-term discontinuation, older age (14), greater severity, and frequency (12) appear associated to persistence of symptoms. Furthermore, psychotic symptoms in adolescents can be important indicators of risk for a range of psychotic (13) and nonpsychotic mental disorders (14–16) as well as conferring greater risk of poorer outcomes (17). In summary, while prevalent and usually transient in nonclinical populations particularly at earlier ages, psychotic symptoms in childhood and adolescents can be predictive of psychopathology later in life (16,18), suggesting that these symptoms probably exist as a continuous phenotype

rather than an all-or-none phenomenon (19).

Childhood-Onset Schizophrenia—Diagnosis, Clinical Presentation, and Differential Diagnoses

Given the relatively high rate of hallucinations in children, with prevalence estimates in large population studies of 8% (20), and reports as high as 21.3% in some community samples (21), the distinction of pathologic psychotic symptoms in childhood is very important. For instance, 28% to 65% of children between the ages of 5 and 12 years of age report experiencing imaginary friends (22) which could be inappropriately misinterpreted as pathologic. Similarly, hallucinations associated with the periods of transition from wakefulness to sleep (hypnagogic) or from sleep to wakefulness (hypnopompic), are frequent in childhood and decline with age (23). It is noteworthy that some cases of sleep-associated hallucinations can be indicative of sleep disorders such as narcolepsy (24).

Although rare, with an incidence in the National Institute of Mental Health (NIMH) cohort of less than 0.04% (25), Kolvin's work established that children can be diagnosed with unmodified criteria for schizophrenia (8,25). Childhood-onset schizophrenia (COS) shows a pattern similar to that of poor-outcome adult cases, and the psychosis of COS can usually be distinguished by its severe and pervasive nature and its nonepisodic, unremitting course (25). Additionally, these children show poorer premorbid functioning in social, motor, and language domains, learning disabilities, and disruptive behavior disorders (26–28), and although not reported in studies of the premorbid history of adult-onset schizophrenia (AOS) (29,30), transient autistic symptoms such as hand flapping and echolalia in toddler years are common (26), probably reflecting more compromised early brain development.

Because COS is rare, it must be distinguished from several childhood conditions that can manifest with psychotic symptoms and/or deterioration in function:

1. Affective disorders: Hallucinations are relatively common in pediatric bipolar disorder and major depression (9,17,31,32). However, the psychotic symptoms in these conditions tend to be mood congruent (33) and follow-up studies on this population generally suggest a less disabling long-term course in a large number of cases (34,35).
2. Psychosis due to medical conditions such as migraine (36), inborn errors of metabolism (37), and substance abuse disorders (38) should be carefully ruled out.
3. Autism spectrum disorders and childhood disintegrative disorder can often be mistaken for psychosis, as they show severe impairment in reciprocal communication, social interactions, and odd stereotyped behaviors (39,40).
4. Conduct disorder and various other behavioral disturbances can be associated with hallucinations (41,42).

5. Atypical psychosis is an important differential diagnosis and is described in detail below.

Atypical Psychosis

A sizeable, heterogeneous group of children referred to the NIMH COS study over the past 20 years had transient psychotic symptoms and multiple developmental abnormalities, but were not adequately characterized by existing DSM-IV categories and were given a provisional diagnosis of "multidimensionally impaired (MDI)" (43–45). In the DSM nosology, these patients might be considered as having either psychosis NOS or mood disorder NOS.

The MDI group, although showing similarities with COS, has distinct features which were used as the operational diagnostic criteria by the NIMH group (43,44) including:

1. Brief, transient episodes of psychosis and perceptual disturbance, typically in response to stress (as opposed to the pervasive hallucinations/delusions in COS)
2. Nearly daily periods of emotional lability disproportionate to precipitants
3. Impaired interpersonal skills despite the desire to initiate peer friendships (distinction from COS)
4. Cognitive deficits as indicated by multiple deficits in information processing
5. No clear thought disorder (although this can be difficult to define clinically, particularly in the presence of a communication disorder)
6. Comorbid ADHD

The MDI children resemble syndromes such as the borderline syndrome of children, or the multiple complex developmental disorder (MCDD) (45–48). However, these syndromes have more predominant symptoms of autism spectrum disorders; greater evidence of a formal thought disorder; and onset before age 5 (as opposed to about age 8 for the MDI group) (44,45,49,50).

Initially, the neuropsychologic test profiles, smooth pursuit eye movement (SPEM) abnormalities, and familial risk factors suggested that some of the MDI children fell within the schizophrenia *spectrum* (44), but the MDI cohort appears to have a distinct long-term clinical course, and none have progressed to schizophrenia (51).

The NIMH COS Experience

The NIMH COS study has been ongoing since 1990. Inclusion criteria for the study are as follows: onset of psychosis before 13, premorbid IQ of 70 or above, and absence of significant neurologic disorder. In the last 24 years, over 2,000 charts have been reviewed, of which 80% are declined from further consideration as they fail to meet criteria for COS. About 400 children have been screened in person, of

whom about 60% receive other psychiatric diagnoses, such as affective disorders, anxiety, or behavioral disorders. About 250 children who appeared likely to meet criteria for COS have been admitted to the research unit and undergone a complete medication washout followed by 1 to 3 weeks' drug-free inpatient observation. An additional 40% did not meet criteria for COS, most frequently because a diagnosis of affective disorder was made (5,43,52). A 4- to 6-year follow-up study of 33 of the ruled-out cases indicated good stability of the alternative diagnoses and confirmed the absence of schizophrenia (53).

PHENOMENOLOGY AND NEUROBIOLOGY OF COS

Premorbid Development

A striking phenomenologic feature of COS relative to AOS appears to be the higher rates of early language, social, and motor developmental abnormalities, possibly reflecting greater impairment in early brain development. In the NIMH COS sample, premorbid development (defined as development prior to 1 year before psychosis onset and assessed using the Cannon-Spoor Premorbid Adjustment Scale (PAS) (54) and the Hollis premorbid development scale (27) and social, speech and language impairments were clearly impaired (55,56), as has been previously observed by other independent research centers (27,28,57,58).

Risk Factors

Since COS represents a more severe phenotype of schizophrenia than AOS, our initial hypothesis was that most risk factors identified in adult studies would be more striking in our very early-onset cases.

Parental Age and Obstetric Complications

AOS studies suggest associations of the illness with advanced paternal age (59–63), raising the possibility of increased de novo mutations in the paternal germ cells, and also increased rates of maternal/fetal obstetric complications (64–66). The NIMH COS cohort showed no correlation with maternal or paternal age (67). In our cohort, we compared the obstetric records of 60 children with COS and 48 healthy siblings using the Columbia Obstetrics Complication Scale (68), a comprehensive measurement scale consisting of 37 variables. Contrary to our hypothesis, the incidence of obstetric complications in COS patients did not differ from that for the healthy sibling control group (69).

Eye Tracking

SPEM abnormalities have been reported in 25% to 40% of first-degree relatives of schizophrenia patients (70). Other studies have suggested more striking abnormalities in COS than in AOS, with a bilineal pattern of inheritance (71). Our group compared 70 COS parents, 64 AOS parents, and 20 COS siblings to separate matched control groups and found that the effect sizes for SPEM abnormalities were higher for COS than for AOS relatives, indicating that genetic factors underlying eye-tracking dysfunction may be more salient for COS (72).

Familial Schizophrenia Spectrum Disorders

Schizophrenia spectrum disorders consist of schizophrenia and schizoaffective disorders on axis I, and schizotypal, paranoid, and schizoid personality disorders on axis II (73). A prior study by Asarnow et al. (74) showed higher rates of schizophrenia spectrum diagnoses for COS relatives than for relatives of patients with attention-deficit hyperactivity disorder (ADHD) or community controls. Similarly, our analyses of 97 parents of COS patients, 97 parents of AOS patients and matched community controls, found a higher rate of familial schizophrenia spectrum disorders in COS than AOS, with the lowest rate in community controls. This observation further supported the continuity between COS and AOS, and the salience of familial/genetic risk in COS (75).

Familial Neurocognitive Functioning

It is well documented that subtle cognitive deficits, including abnormalities of attention (76,77), executive functioning (78,79), spatial working memory (80), and verbal memory (81,82) are seen in healthy relatives of patients with AOS (83–85). Deficits in auditory attention, verbal memory, and executive functioning are generally considered consistent (86,87), although it is unclear whether these represent an underlying global cognitive deficit or each deficit represents a discrete endophenotype transmitted in families of patients with schizophrenia (78,86). When we compared neuropsychologic deficits in 67 parents and 24 full siblings of COS patients to matched community controls in the Trail Making Tests A and B and the Wechsler Intelligence Scale-Revised Digit Span and Vocabulary, COS siblings had significantly poorer performance than community controls, although the rates of neuropsychologic abnormalities for COS were not significantly higher than for AOS (88).

Pervasive Developmental Disorder and COS

The diagnosis of autism or pervasive developmental disorder (PDD) has been raised early in the development in our cases (n = 28 of 97, 28%) (26) and several studies have claimed that autism per se might be a risk factor for later psychosis (89–92).

Premorbid PDD may be a nonspecific manifestation of impaired neurodevelopment, and also may provide an independent additive risk factor for COS. We ascertained the premorbid diagnosis of past or current autism or PDD in 97 COS probands in whom the diagnosis of PDD was made according to DSM-IV criteria (American Psychiatric Association, 1994) based on early chart reviews and clinical interviews of patients and parents. The diagnoses of PDD was made in cases in which there was a clear clinical history of symptoms of autistic/PDD spectrum prior to the onset of psychosis that were still observable at the time of the NIH evaluation.

Twenty-eight (29%) of our COS patients had a lifetime diagnosis of PDD: 3 met criteria for autism, 1 for Asperger disorder, and 24 for PDD NOS (26). Premorbid social impairment was the most common feature for COS-PDD subjects; the PDD group did not differ significantly from the rest of the COS sample with respect to SES, age of onset, IQ, or severity as measured by the Global Assessment of Severity (GAS). However, similar to demographic characteristics seen in the literature for children with PDD, the COS patients with PDD were predominantly male ($p = 0.04$) and non-African American ($p = 0.02$) (26). In an earlier study, our group also failed to find any differences in baseline or 2- to 6-year clinical outcome measures, parental SES, response to medications, and rate of familial schizotypy (56). Furthermore, there was no difference between PDD and non-PDD groups with respect to initial brain magnetic resonance imaging (MRI) measures after controlling for gender, although the rate of gray matter (GM) loss appeared to be greater for PDD ($n = 12$) than for the non-PDD ($n = 27$) subgroup (−19.5 ± 11.3 mL/yr vs. −9.6 ± 15.3 mL/yr; $p = 0.05$) (56). These results may indicate that PDD in COS may be a nonspecific marker of more severe early abnormal neurodevelopment. However, siblings of the PDD-COS patients had significantly higher scores on the autism screening questionnaires, and 2 of 12 (17%) siblings of PDD patients were diagnosed with autism, a total rate similar to that seen for sibling of autistic patients (4.9%) (93), which may still imply a familial–genetic connection between COS and autism.

Neurocognitive Functioning in COS Patients

Neuropsychologic function in COS outpatients has been studied by Asarnow et al. (94–96). While rote language skills and simple perceptual processing are not impaired, these children perform poorly on tasks involving fine motor coordination, attention, short-term and working memory (97). Evoked potential studies show diminished amplitude of brain electrical activity during these tasks, suggesting that allocation of necessary attentional resources is deficient, which is also shared by adults with schizophrenia (96). It is generally established for adult schizophrenia that cognitive function deteriorates at onset of psychosis but remains stable afterward (98–100). Our earlier study had shown that children with COS ($n = 27$) as well as

those with MDI (n = 24) share similar deficits in attention, learning, and abstraction, resembling the pattern in adult patients with schizophrenia (101). A subsequent analyses of 71 COS patients where preadmission IQ data were also available from medical and school records for a subgroup (n = 27), pre- and postpsychosis decline in IQ was noted as for adults, but postpsychotic cognitive function for up to 8+ years did not show continued decline (Fig. 5.3.1). Thus, in spite of greater severity and generally poor clinical outcome, there was no evidence for a longer-term degenerative cognitive process in COS, at least through early adulthood (102).

Comorbid Disorders

Comorbid psychiatric disorders, particularly DSM defined mood, anxiety, and substance abuse disorders, often coexist with schizophrenia and can significantly alter the presentation, clinical course, or prognosis of the illness (103–106). As the symptom manifestations of these disorders can also be part of (or masked by) the symptoms of the primary illness, the diagnoses of independent axis I conditions are often ignored (107–109). Furthermore, medical comorbidities in schizophrenia are also frequent (110), including cardiovascular disease (due to tobacco, diabetes, obesity, and increased lipids), HIV, and infectious hepatitis (111). We analyzed the rate of coexistent axis I diagnoses for 76 COS cases at the time of first NIMH admission, and correlated the comorbid diagnoses with age of onset, ratings of illness severity, familiarity, and premorbid development.

As seen with AOS, the most frequent comorbid diagnosis at NIMH screening was depression (54%), followed by obsessive-compulsive disorder ([OCD] 21%), generalized anxiety disorder ([GAD] 15%), and ADHD (15%). The rate of “any” anxiety disorder (GAD, OCD, separation anxiety, PTSD, and panic disorder combined) at screening was 42%. In general, comorbid diagnoses were independent of other illness indices, but comorbid depression correlated with poorer GAS scores (p = 0.01), and presence of an anxiety disorder only predicted anxiety at 4-year follow-up (p = 0.05). No other psychiatric diagnoses showed correlations with any clinical measures, and there were no significant associations between comorbid diagnoses and IQ, familiarity, medication status, premorbid functioning, or age of onset at psychosis. Interestingly, no “current” comorbid depression was seen at the 4-year follow-up for a subgroup of 28 subjects for whom there was complete diagnostic information available, possibly due to our high use of antidepressant treatment (45%). In contrast, anxiety disorders remained highly comorbid despite adjuvant anxiety medication use, suggesting either the refractory nature of these conditions, or a close association with core schizophrenia pathology.
FIGURE 5.3.1. Full scale IQ measures for 70 COS children plotted before (n = 21) and after (n = 70) the onset of psychosis, and also before (n = 56; obtained from prior charts) and after (n = 70) the children were admitted to the NIMH study. Although the children show significant decline in full scale IQ after the onset of psychosis, there is no significant long-term decline over next 14 years.

BRAIN IMAGING: STRUCTURAL, FUNCTIONAL, AND POSITRON EMISSION TOMOGRAPHY

The majority of the imaging studies of COS come from the NIMH sample, with more recent contributions from other groups (112–115). Using both cross-sectional and longitudinal data, and rapidly developing state-of-the-art brain mapping methods, neuroimaging in COS has addressed some broad questions about brain development in COS and schizophrenia in general.

Structural Neuroimaging

A fundamental question in brain imaging studies of any illness is whether there are overall differences in brain size. Studies in AOS have documented decreased intracranial volume (116,117), longitudinal reduction in total cerebral volume (118), and ventricular enlargement (119). It is also predicted that brain growth in AOS is stunted even before the onset of illness (116). Similarly, in COS patients, overall brain volume at initial scan is smaller and is followed by a progressive decline in volume during adolescence (120). Patients with COS have also been found to have

larger ventricular volume (121) as well as greater progressive increase in ventricular size compared to healthy controls (120,122). Understanding how these brain changes are meaningfully related to clinical features remains an important unanswered question, but collective research points toward the significance of key findings, which are highlighted in the following sections.

Cortical Gray Matter Thickness

Progressive cortical GM loss in COS was first described by Thompson et al. in 2001 (123). This study demonstrated a dynamic wave of GM loss, which started in the parietal and motor cortices and advanced into the superior frontal, dorsolateral prefrontal, and temporal cortices (including the superior temporal gyri). While temporal and dorsolateral prefrontal cortex deficits were among the most severe, they began in late adolescence and were observed only after the onset of psychotic symptoms. The progressive deterioration in GM also correlated with overall deterioration in global functioning. Seeking to determine whether psychosis itself was associated with GM loss, the study included a comparison group of participants with atypical (nonschizophrenic) psychosis, matched for IQ and medications, in addition to healthy volunteers. This atypical psychosis group showed subtle but significantly greater GM loss than healthy volunteers, pointing to a successively increasing rate of GM loss, with COS patients experiencing the greatest loss. In 2004, prompted by the Thompson study, using a similar analysis we evaluated cortical maturation in typically developing children for prospective cortical changes between the ages of 4 to 21 years (124). This study highlighted the timelines of cortical maturation, and importantly, it suggested that COS neurodevelopment appeared to be an exaggeration of normal GM loss and maturation patterns, possibly indicating a loss of inhibitory regulation of the development process (Fig. 5.3.2).

These initial observations generated an important question: Does the GM loss persist into early adulthood and if so, does it continue at the same rate? A longitudinal study addressed this question by following COS patients and controls into adulthood (125). This study found a 7.5% difference in mean cortical thickness (MCT) ($p = 0.001$) between COS patients ($n = 70$, ages 7 to 26) and age-matched healthy controls ($n = 72$), as well as progressive cortical thinning in the parietal, frontal, and temporal regions, although the parietal thinning normalized by early adulthood (125). These results are continuous with findings from AOS patients, which demonstrate cortical thinning in the frontal and temporal cortices only (126,127). Together, these findings established that the profound GM thinning in adolescence appears to slow down as the children mature. Whether this lessening rate is part of the natural course of the disease, a resilience process, or due to medical treatment remains difficult to conclude.

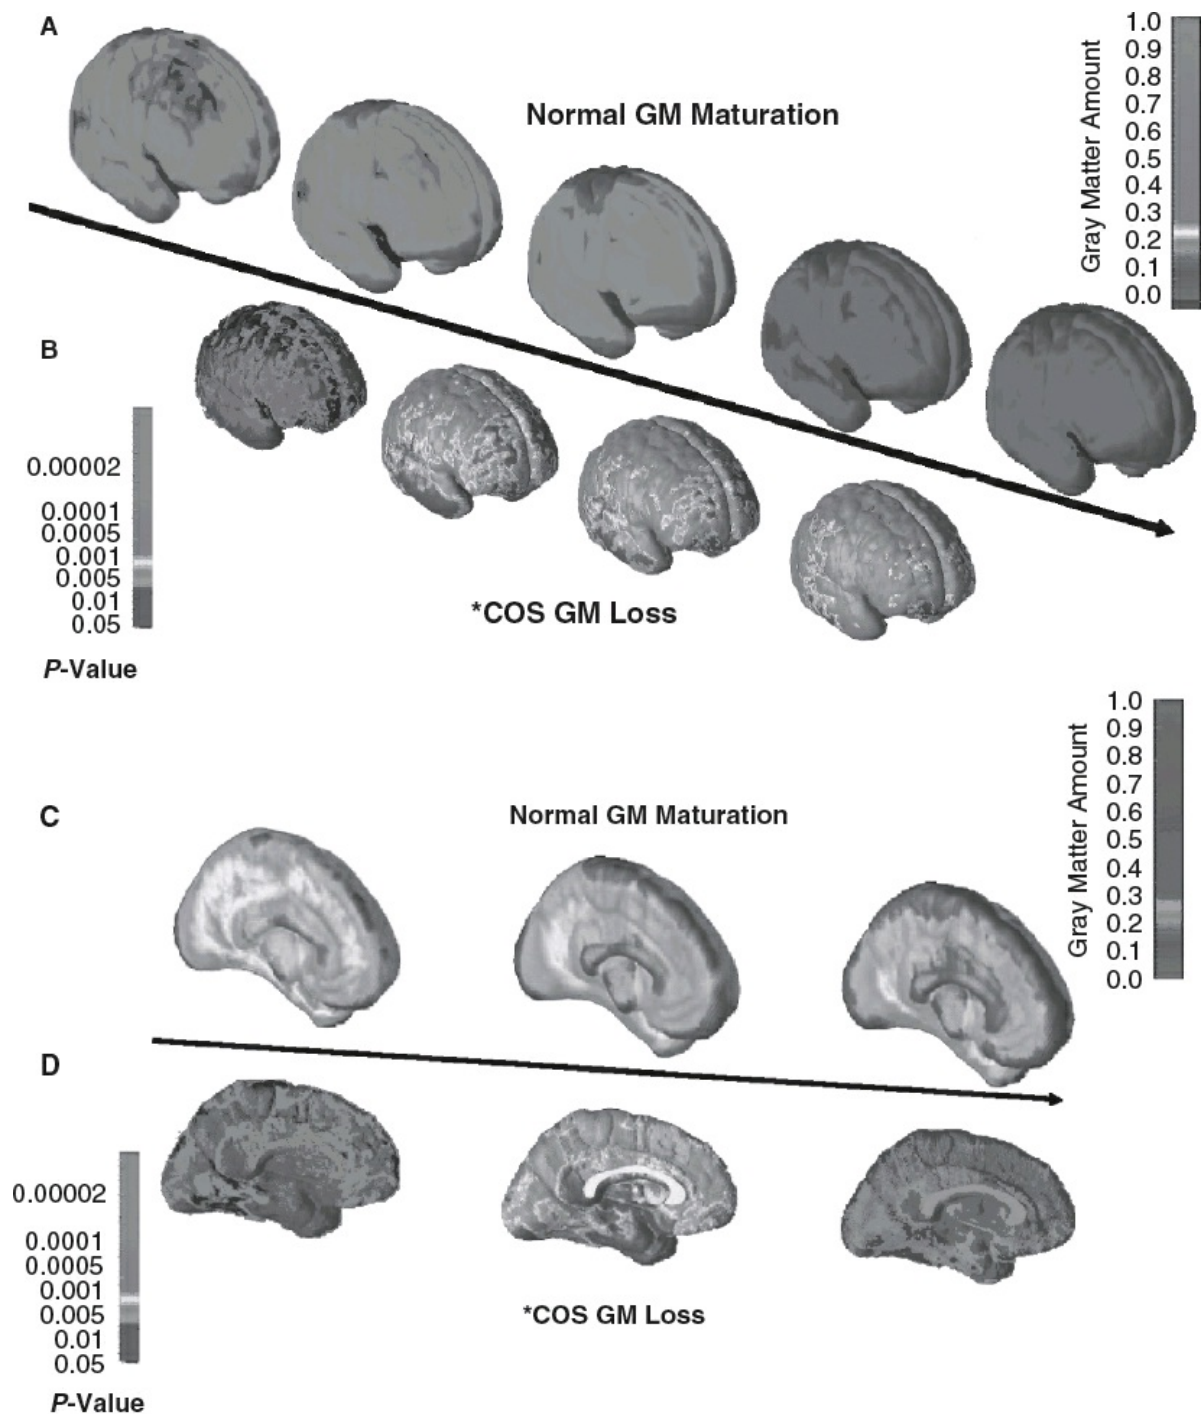
It has also been established that COS patients do not differ from healthy controls with regard to sex differences in cortical thickness (128), or cross-sectional or

longitudinal developmental changes in asymmetry (129). Cortical thickness deficits in COS are also largely uninfluenced by clozapine versus olanzapine intake, aside from a small area of the right prefrontal cortex (130). These findings are consistent with AOS, in which age, dose, or type of antipsychotic medication is not significantly linked to changes in cortical thickness (127).

Subcortical Structures

Hippocampus Critical in learning and memory, the hippocampus has been a structure of significant interest in schizophrenia, where cognitive deficits remain a primary feature of the disease. Deficits in hippocampal volume are well documented in AOS bilaterally (131) and is suggested in COS (120,132).

Prospective studies (133,134) have demonstrated fixed longitudinal volumetric deficits in COS patients compared to controls. Of these, the study with the largest sample (134) (89 COS patients, 78 siblings, and 79 controls) corroborated prior findings (120,133) that suggest that the hippocampal deficits in COS are significant but do not vary over time. These findings are consistent with the animal model of schizophrenia suggested by Lipska et al. in 1993 (135), in which an early fixed deficit in the hippocampus, which is relatively quiescent during the first years of development, manifests later during periods of increased stress or with exposure to particular substances.

Anatomically, subregional shape abnormalities of hippocampus have also been described in AOS (136,137) and COS (138). Bilateral inward deformations of the anterior hippocampus have been found in COS (138), and greater differences have been associated with increased symptom severity. The affected hippocampal regions are commonly associated with hippocampal CA1 pyramidal neurons, whose migration is disrupted by genetic differences associated with schizophrenia (e.g., disruption of the Disc1 gene) (139). The CA1 neurons serve as a connection between the hippocampus and the prefrontal cortex, which is also widely implicated in schizophrenia (140). While the exact involvement of hippocampal abnormalities in COS is unclear, it is possible that abnormal neurodevelopment in these interconnected regions holds further information regarding symptom development.


*Data on Childhood Schizophrenia only age 12 to 16

FIGURE 5.3.2. Comparison of the patterns of cortical GM loss in COS (between ages 12 and 16) to that seen in normal cortical maturation (between ages 4 and 22). (**A,C**) Lateral and medial views of the dynamic sequences of cortical GM maturation in healthy children between ages 4 and 22 (n = 13; 54 scans) rescanned every 2 years. Scale bar shows GM amount at each of the 65,536 cortical points across the entire cortex represented using a color scale (red to pink—more GM; blue—GM loss). Cortical GM maturation appears to progress in a back to front (parietotemporal) manner on the lateral surface and in a top-down fashion on the medial surface. (**B,D**) Lateral and medial views of

the dynamic sequence of cortical GM maturation in COS between ages 12 and 16 compared with age- and sex-matched healthy controls (*n* = 12; 36 scans in each group), where children are rescanned every 2 years. Dynamic maps represent *p*-values for the difference in GM amount between COS and controls at each of the 65,536 cortical points, and *p*-values are represented using a color scale (e.g., pink $p < 0.00002$) which can be observed in color in the original paper or in the online figure. Cortical GM loss in COS also appears to follow in a back to front direction on the lateral surface and in top-down direction on medial surface, thus suggesting that the COS pattern is an exaggeration of the normal GM maturation. (Adapted from Gogtay N, Giedd JN, Lusk L, et al.: Dynamic mapping of human cortical development during childhood through early adulthood. *Proc Natl Acad Sci USA* 101(21):8174–8179, 2004; Thompson PM, Vidal C, Giedd JN, et al.: Mapping adolescent brain change reveals dynamic wave of accelerated gray matter loss in very early-onset schizophrenia. *Proc Natl Acad Sci USA* 98(20):11650–11655, 2001.)

Cerebellum The cerebellum has a highly heritable development (141), may contribute to higher cognitive functions (142), and it is a potential key site of dysregulated circuitry in schizophrenia (143). In line with this, cerebellar deficits have been linked to COS (144). An early cross-sectional study of COS patients between the ages of 9 and 18 demonstrated decreased cerebellar volume relative to controls in the vermis (11.7% smaller), midsagittal inferior posterior lobe area (10.9% smaller), and midsagittal inferior posterior lobe (8.9% smaller) (145). Studies of AOS have reported a progressive decline in cerebellar volume (146), or a smaller cerebellar volume during the first episode in AOS (147).

In a prospective study of COS patients (*n* = 94) ages 6 to 29 and their nonpsychotic siblings (*n* = 80), COS subjects had smaller bilateral anterior lobes and anterior and total vermis volumes compared to controls (148). Siblings did not differ from healthy controls initially, but demonstrated decreased cerebellar volume over time in the total and right cerebellum, left inferior posterior, left superior posterior, and superior vermis (148). The presence of cerebellar deficits in healthy siblings of COS patients, as well as the presence of abnormalities in AOS patients during the first episode, suggests that the cerebellar trajectory described is likely related to a genetic risk for schizophrenia.

White Matter The dysconnectivity hypothesis of schizophrenia first proposed that aspects of the illness could be due to abnormal (increased or decreased) connectivity between brain regions as opposed to localized abnormalities within regions (149).

Studies of white matter provide initial insights into the dysconnectivity hypothesis. White matter abnormalities have been demonstrated in both AOS and COS patients. Using tensor-based morphometry, we demonstrated that teenage COS patients have a slower rate of white matter growth per year, particularly in the right hemisphere, and that growth deficits are associated with lower functioning in terms of the GAS (150). AOS patients show similar white matter deficits longitudinally (117).

Diffusion tensor imaging (DTI), which examines directional diffusion of water in the brain to infer the structural integrity of neural fibers, has led to less conclusive results. In the largest study of DTI in COS to date, examining eleven regions of interest, we found decreased white matter integrity in the bilateral cuneus, a portion of the occipital lobe (151). In another DTI study, COS patients exhibited a decrease in white matter integrity in relation to their level of linguistic impairment (152). Overall though, DTI research in COS is limited, and inconsistent with the frontal abnormalities demonstrated by AOS DTI research (153); more observations with larger samples and better image resolution are likely required to provide clearer insight into potential white matter alterations in COS.

Corpus Callosum The majority of patients with schizophrenia manifest neurologic soft signs that include errors in sensory integration, motor coordination, and inhibition (154). These processing deficits, which may arise partly from decreased interhemispheric neural communication, have been associated with irregularities in the corpus callosum (155) and meta-analyses have generally established a reduced midsagittal cross-sectional area in the corpus callosum (156,157). First episode patients showed decreased corpus callosum areas, while chronic patients were more likely to demonstrate an increase in the area (156). The only longitudinal study of the corpus callosum in AOS schizophrenia patients demonstrated progressive decline in callosal size, with poor-outcome patients showing more pronounced decline (158).

The largest to-date longitudinal study in COS (159) (n = 98), their siblings (n = 71), and healthy controls (n = 100) found no differences in total corpus callosum or in the area of any subregion cross-sectionally or in developmental trajectories of any measurement of corpus callosum area or volume (159). Similarly, a study examining healthy siblings of COS patients found no significant differences in corpus callosum area (159). These data suggest that the behavioral deficits in sensorimotor integration in COS may originate not in callosal connections but in the interaction of multiple networks, possibly reflecting a dysfunction in predictive processing (160–162).

Functional Magnetic Resonance Imaging

Functional imaging studies are difficult to conduct in the COS due to illness severity, which make it difficult for patients to perform tasks in the scanner and often introduce behavioral confounds. In a unique fMRI study of language processing in COS,

Borofsky et al. (163) found that COS patients have overall reduced activity compared to healthy controls during both semantic and syntactic language processing tasks. The differences in activation were not related to performance on the task, as there were no group differences in success rate.

Resting state fMRI (R-fMRI) studies have been relatively more feasible in COS. R-fMRI has been used to examine dysconnectivity in AOS using various methods, and support the dysconnectivity model of schizophrenia (164). To date, the four published studies of R-fMRI in COS are from the NIMH sample (165–167) and demonstrate decreased local connectivity strength in COS that is partially balanced by increased global network efficiency relative to healthy controls (166,167). Furthermore, we found widespread decreased functional correlations in COS patients compared to healthy volunteers, in brain regions that organized into a social-cognitive and a sensorimotor processing network. These findings emphasized the role of dysfunctional integration of these two major systems, and importantly, found that resting state alterations were linked to behavioral symptoms. Specifically, decreases in functional connectivity across these two networks in COS were related to the severity of positive symptoms, while connectivity decreases within the social-cognitive network related to the severity of negative symptoms (165). These results are consistent with the proposal that dysfunctional network interactions play a crucial role in the disease, particularly with respect to sensorimotor integration and predictive processing.

Healthy Siblings

Studying nonsymptomatic or healthy siblings of patients with heritable illnesses improves understanding of the contribution of genetic background to an illness state versus an illness predisposition or trait. Nonpsychotic biologic full siblings of COS patients, share about 50% of their genetic material and can add valuable context to neuroimaging findings (168). In the most simplified form, consistent phenotypic differences between patients and their healthy biologic full siblings suggest that the patient phenotype is related to the expression of symptoms (disease state), assuming that the healthy sibling group and unrelated healthy control group do not differ. On the other hand, similarities between healthy and ill siblings, despite the difference in their health status, can relate phenotypes to genetic vulnerability that may not contribute directly to symptoms (disease trait). Due to the early-onset nature of COS, siblings of COS patients enter studies at early ages and thus provide a unique opportunity to address questions of state versus trait within a neurodevelopmental window.

State Markers

State markers are characteristics unique to the expression of symptoms that do not occur in unrelated healthy controls or healthy siblings of patients despite their predisposition for the illness. Because these differences occur despite similarities in genetic background between patients and their unaffected siblings, they are assumed to be associated with the development of the disease, for example, psychosis in the case of schizophrenia. The brain area most consistently identified as a state marker for schizophrenia through COS studies is the hippocampus, which demonstrates volumetric deficits, that are fixed over time, in patients but not their nonpsychotic siblings (134).

Trait Markers

Trait markers are defined as phenotypes that may be related to predisposition for the illness, but may not be directly related to the disease. Nonpsychotic siblings of COS patients share a number of characteristic abnormalities with their affected relatives, including differences in cerebral volume, GM thickness, and white matter growth (169–171). Two nonoverlapping studies of unaffected siblings (n = 52; ages 8 to 28 and n = 43, ages 5 to 26 years) versus healthy controls (n = 52 and n = 86) demonstrated no significant difference in MCT between the two groups, however the sibling group had a pattern of early restricted GM loss (171,172). Both studies examined cortical thickness in siblings by region, revealing GM deficits in prefrontal, temporal, and parietal areas during early life. Each of these deficits, though initially similar to those seen in young COS patients, were undetectable by adulthood (171,172) (Fig. 5.3.3). This deficit "normalization," which is likely to be an age-specific trait marker, may also help explain inconsistent results from studies of cortical thickness in healthy siblings of AOS patients (173) where the average age of sibling sample is much older and past the developmental window. Furthermore, siblings of COS patients have also been shown to exhibit deficits in white matter growth during adolescence at early stages in life, however the growth rate normalizes by adulthood in healthy siblings, suggesting that white matter growth may also represent a trait marker (170).

FIGURE 5.3.3. Cortical GM development in healthy COS siblings (n = 56; 100 scans) compared with age- and sex-matched normal volunteers (n = 56; 100 scans) between 6 and 30 years. Analyses were done using automated cortical thickness measure across 40,000 cortical points over the entire cortex using mixed-effect regression model analyses which allowed using cross-sectional as well as longitudinal scans. Color bars, which can be observed in color in the original paper or in the online figure, represent t-

statistics where t > 2 (adjusted for multiple comparisons, using false discovery rate at t = 2) indicates significant loss of GM in healthy siblings compared to controls at that cortical point. GM differences at various ages were obtained by age recentering the data at that age. Healthy siblings showed GM loss in prefrontal and temporal cortices in early ages, but the GM differences were normalized by age 24 years. Images are shown both with and without adjusting for mean cortical thickness (MCT). (From Gogtay N, Greenstein D, Lenane M, et al.: Cortical brain development in nonpsychotic siblings of patients with childhood-onset schizophrenia. *Arch Gen Psychiatry* 64(7):772–780, 2007.)

To date, a single task-based fMRI study has been reported in a COS sibling population which demonstrated that healthy siblings of COS patients showed aberrant frontal and striatal activation relative to healthy controls during a cognitive skill learning task (174). If feasible, it would be interesting to conduct a similar study in COS patients, in order to understand to what extent these findings may represent a functional endophenotype.

To our knowledge, no R-fMRI studies have been published describing functional connectivity in healthy siblings of COS patients although preliminary findings from our unpublished data suggest they are intermediate, similar to that seen for structural abnormalities, suggesting a potential functional trait marker.

Genetic Studies

Schizophrenia is a complex disorder with a heterogeneous phenotype in which most likely numerous genetic and environmental exposures are involved (175). While inheritance patterns vary, a strong genetic inheritance is supported by twin, family, and adoption studies (175,176). Observations across pediatrics and medicine suggest that early-onset cases may have more salient genetic causes (4,177,178), and as with breast cancer (179), Alzheimer disease (180), and type II diabetes (181), the familial risk for schizophrenia spectrum disorders appears higher for COS than in AOS contrast groups (74,75).

In genetic studies of complex disease there are currently two salient working hypotheses, the common disease–common allele model, which proposes that combinations of common genetic variations (i.e., polymorphisms in >1% of the population) contribute a modest effect to disease cause or susceptibility (182). Alternatively, the common disease–rare allele hypothesis proposes that some individually rare mutations (<1% of the population, which a single individual or family may have) with high penetrance contribute to disease cause or susceptibility (183).

Common Variant Alleles

While now considered generally inadequate, earlier studies of common variants focused on candidate genes, which utilized existing biologic knowledge to identify single-nucleotide polymorphisms (SNPs) as markers to map and trace transmission of regions of the chromosome (182). One of the key issues about this approach is that many disease genes have been unanticipated based on what was previously known. Notwithstanding, using the hypothesis that there may be more detrimental/penetrant mutations in known schizophrenia susceptibility genes in COS, several genes previously implicated in AOS samples showed significant association with COS including G72 (now DAOA) (184), neuregulin 1 (NRG1) (185), GAD1 (186), and dysbindin (DTNBP1) (187). In addition to supporting the genetic continuity between COS and AOS, these data suggested that the very early-onset COS population, with more pronounced neurobiologic abnormalities and a more homogeneous phenotype, might turn out to be a relatively efficient population to target for the identification of genetic risk of schizophrenia more generally.

With the technologic advances in microarray analyses, genome-wide association studies (GWASs) have opened a new window into the genome at a submicroscopic level by systematically assessing a broad array of SNPs independent of prior scientific knowledge (188). Because GWASs require stringent corrections for multiple comparisons, studies must have very large numbers of participants/samples in order to be adequately powered. This encouraged international collaborative efforts such as the Psychiatric Genomic Consortium (PGC) in order to pool samples. Despite these efforts, samples for rare diseases such as COS remain small with pooled numbers of less than 300 which cannot compare to AOS studies of over 16,000 patients (189). Results from large GWAS studies in AOS have included the association of the major histocompatibility complex and the intron 4 transcription factor (TCF4) involved in neurogenesis and brain development (190). GWAS results have also supported polygenicity, with multiple small genetic variations conferring risk for AOS, genetic overlap with other mental illnesses, and difficulties replicating findings from prior candidate gene studies (191–193). To overcome the issue of small sample size, the NIMH team created polygenic risk scores for 130 COS participants and their healthy sibling controls, using 80 genomic variants associated to schizophrenia PGC GWAS. Despite the small sample size, COS participants had higher risk scores than their healthy siblings ($p < 0.05$). Although only with the most liberal significance threshold, the study also described overlap between polygenic risk for autisms and COS (194).

Rare Variant Alleles

Studies of rare variant alleles have focused primarily on structural variations in

stretches of DNA known as copy number variations (CNVs). Essential to these studies is that these types of variations are common in human populations and, while they may denote disease risk, they may also represent standard genetic variation. One of the initial seminal studies of CNVs in schizophrenia found a progressive increase in novel CNVs with earlier age of onset of schizophrenia. While only 5% of the controls had any CNVs >100 kb, 15% of AOS cases and 20% of young onset (< age 18) had CNVs. An independent replication in the same study found that 28% of COS patients had CNVs compared to 13% in their control sample of COS parents. A large number of the CNVs affected genes in brain development and regulation pathways (183). This study was followed by numerous additional findings of CNVs in schizophrenia (195–200). Using whole genome sequencing, the NIMH team assessed CNVs in 126 COS patients and 69 of their healthy full siblings. Focusing on a group of 46 CNVs associated to risk for AOS, autism, intellectual disabilities, and seizures, the study found that COS patients had not only significantly higher rates of disease-related CNVs compared to their healthy sibling controls ($p = 00.17$), but also than that reported in AOS ($p < 0.0001$) (201).

Cytogenetic Abnormalities

High-resolution banding karyotype and fluorescent in situ hybridization (FISH) analyses are done routinely on all COS participants to look for fragile X, 22q11 deletions, Smith–Magenis (17p11.2del), and 15q11–q13 deletions/duplications. Almost 10% of the NIMH COS participants show chromosomal abnormalities. The 22q11 deletion syndrome (22q11DS), manifest as velocardiofacial syndrome (VCFS), is estimated to occur 1 in 4,000 live births (202), and is a known risk factor for schizophrenia (203,204). Five out of 126 (4.0%) of the NIMH COS patients have VCFS with spontaneous 22q11.2 deletion, a rate significantly higher than reported in healthy controls (0.2%) ($p < 0.0001$) (205), AOS patients (0.3% to 1%) (206–208) ($p < 0.0001$), or any clinical population at present. Despite the association between autism and the 22q.11.2 deletion (209,210), and the presence of prepsychotic autism spectrum disorders in 20% of our sample, none of the individuals with the 22q11.2 deletion had prepsychotic autism symptoms (201). Similarly, 7 out of 133 have large chromosomal abnormalities such as Turner syndrome, XYY, trisomy X, or either translocations or frameshift mutations (211,212).

TREATMENT STUDIES IN CHILDHOOD PSYCHOSES

Although rare, COS is a devastating disorder, frequently resistant to treatment, and with an unfortunately narrow evidence base to guide treatment, particularly as there are few trials comparing atypical antipsychotics, which have become the mainstay of current treatment (213). Two prior randomized controlled trials established the

superiority of typical antipsychotics over placebo in COS (214,215). A single trial in a small group of treatment refractory COS patients had demonstrated the efficacy of clozapine over the typical antipsychotic haloperidol (216). However, as there was no placebo arm in the study, it is hard to assess the true effect size for clozapine. A later double-blind randomized controlled trial of comparing clozapine (n = 12) with olanzapine (n = 13) showed a significant advantage for clozapine in the alleviation of negative symptoms of schizophrenia, which was not correlated with improvement in mood or extrapyramidal side effects. As anticipated, clozapine was associated with more overall side effects, including enuresis, tachycardia, hypertension, and significant weight gain by 2 years (217). The results of the NIMH cohort and studies in AOS patients (218,219) show that clozapine has the greatest antipsychotic efficacy, particularly in a pediatric population, with our recent study finding over 70% of the 120 children available at follow-up adhering to clozapine treatment for more than 2 years, despite its side effects and need for close monitoring (220).

Adverse Effects of Clozapine

In spite of its unique efficacy for some COS patients, clozapine is associated with several side effects, in particular agranulocytosis, weight gain, cardiovascular changes such as postural hypotension and tachycardia, and incontinence. The NIMH study has started addressing the questions of how to manage these side effects so that these children can continue to stay on clozapine.

Neutropenia and Akathisia

Children and adolescents treated with clozapine have increased susceptibility to neutropenia, particularly in male children with African American decent (221). This can be successfully managed by addition of lithium (222). Similarly, akathisia, seen only rarely in adults on clozapine, appears more common in children and can frequently manifest as worsening of psychotic symptoms or agitation in children, which frequently results in dosage increment. This side effect is responsive to adjunctive propranolol treatment (223).

Weight Gain

Weight gain is a significant effect of atypical antipsychotics and appears more pronounced in pediatric patients (224,225). Clozapine particularly has been noted to cause significant weight gain during childhood (226). Although the mechanism of weight gain in poorly understood, genetic risks (polymorphism in beta 3 and alpha-1A adrenergic, 5HT-2C, TNF-alpha, and histamine receptors) and a number of biochemical correlates (e.g., leptin, prolactin, triglyceride, and HDL levels) of weight gain have been reported in the literature (227). In our group, an analysis of 23

COS patients treated with clozapine and 21 matched healthy controls showed increases in BMI ($p < 0.001$) and leptin levels ($p = 0.003$) after 6 weeks of treatment. For COS patients, BMI at baseline and week 6 correlated with insulin level ($r = 0.5, p = 0.004$) and BMI was positively correlated with clinical improvement in CGI, SAPS, and SANS rating scales ($p < 0.05$) (228). Based on these correlations, we have used the antidiabetic medication metformin (which improves peripheral insulin sensitivity) with some success although no formal trial was done.

5.4 MOOD DISORDERS

CHAPTER 5.4.1 ■ DEPRESSIVE DISORDERS

DAVID A. BRENT

In this chapter, we describe the nosology and epidemiology of unipolar depressive disorders in youth, risk factors for depression onset and recurrence, and the evidence base for psychosocial and pharmacologic treatments. We conclude with suggested areas for future inquiry.

CLINICAL PICTURE

Depressive disorders in childhood and adolescence are characterized by core persistent and pervasive sadness, anhedonia, boredom or irritability that is functionally impairing, and relatively unresponsive to usual experiences that might usually bring relief, such as pleasurable activities and interactions and attention from other people. The single most important distinction between depression as an illness and the "normal ups and downs" of childhood and adolescence is that depression is associated with functional impairment, mediated through the intensity, duration, and lack of responsiveness of depressed mood and associated symptoms.

Depressive disorders exist on a continuum, and are classified on the basis of severity, pervasiveness, and presence or absence of mania (1). At the mildest end of the spectrum are adjustment disorders with depressed mood, which are mild, self-limited, and occur in response to a clear stressor. Other specified depression, which has sufficient duration (at least 2 weeks) and impairment, but fewer symptoms than major depression, also referred to as "minor" or sub-syndromal depression, and is diagnosed in the presence of depressed mood, anhedonia, or irritability, and up to three symptoms of major depression (2). Persistent depressive disorder, which in DSM-5 replaces dysthymic disorder, is a chronic depressive condition with fewer symptoms than major depression, but lasts a minimum of 1 year. Major depression requires the greatest number of symptoms, with either sad or irritable mood, or anhedonia, along with at least five other symptoms, such as social withdrawal, worthlessness, guilt, suicidal thoughts or behavior, increased or decreased sleep, decreased motivation and/or concentration, and increased or decreased appetite. Rarely, young patients with major depression also have psychotic symptoms such as auditory hallucinations or delusions, usually with self-derogatory, paranoid, or depressive content. Depression may be seasonal in onset, typically beginning in the fall when exposure to sunlight decreases.

There is one new mood-related condition in DSM-5, termed disruptive mood dysregulation disorder (DMDD), which is characterized by severe, persistent irritability, namely, at least three temper outbursts weekly, and has its onset in youth aged 6 and no older than age 10. According to DSM-5, if the symptoms of DMDD

are present, one cannot make a diagnosis of oppositional defiant disorder (ODD). However, if hierarchical diagnostic procedures are not applied, DMDD shows extremely high diagnostic overlap with ODD and mood disorders, and in the National Comorbidity Survey, Adolescent Supplement (NCS-A), its 12-month prevalence shrinks from 5.2% to 0.12% (3,4).

Comorbidity is the rule rather than the exception in depressed children and adolescents, especially in clinical samples (5). Anxiety is frequently a precursor of mood disorder and may also occur simultaneously with depression (6). The relationship between behavioral disorders, such as ADHD and conduct disorder is in part mediated by their comorbidity with ODD, which is a strong predictor of eventual depression (6). Alcohol, tobacco, and cannabis use and abuse are highly comorbid with depression, but longitudinal analyses suggest that alcohol and substance use are more likely to precede and lead to depression, than vice versa (7–9).

DESCRIPTIVE EPIDEMIOLOGY

Estimates of Population Prevalence

The point prevalence of depressive disorders is 1% to 2% for prepubertal children and in the National Comorbidity Survey, Adolescent Supplement, the lifetime and 12-month prevalence for adolescent depression were 11.0% and 7.5%, respectively (10,11).

Gender Distribution and the Onset of Puberty

The 3:1 female predominance in mood disorders first emerges in adolescence (10). The higher female-to-male rate of depression after the onset of puberty may be due to higher rates of anxiety disorder and a tendency to rumination in females, and greater sensitivity to interpersonal stressors in females, all of which predispose to depression (12). Early onset of puberty increases the risk of depression in girls (13). Other peripubertal developmental factors that may contribute to an increased risk of depression after puberty include changes in prefrontal and limbic circuitry involved in emotion regulation, social attribution, and reward, as well as a greater incidence of sleep deficit and experimentation with drugs and alcohol (7,8,14,15).

Age and Developmental Factors

Most typically, prepubertal depression has a set of risk factors and course similar to conduct disorder, characterized by family discord, parental criminality, and parental substance abuse, and increased risk of antisocial disorder, but not depression in adult

life (16). Less commonly, prepubertal depression is highly familial, with multigenerational loading for depression, with high rates of anxiety and bipolar disorder, and recurrences of mood disorder in adolescence and adulthood (17). Adolescent-onset depression is more likely to result in recurrent episodes in adult life (16,17). Depressive disorders have been reported in preschool children, with evidence of strong family loading for depression, and continuity of depressive disorders into later childhood (18).

RISK FACTORS FOR DEPRESSION ONSET AND RECURRENCE

Genetic

Twin studies demonstrate that depressive symptoms have a heritability of around 40% to 65%, with higher estimates of heritability in adolescent versus prepubertal children (19). Both "bottom-up" and "top-down" family studies have shown a two- to fourfold increased risk of depression in first-degree relatives (20). Greater family loading, either due to both parents having depressive disorders, or having an affected parent and an affected grandparent further increase the likelihood of depression in offspring (20).

Possible intermediate phenotypes that might account for the familial transmission of depression include traits of fearfulness, cognitive bias toward sad emotional stimuli, difficulty with mood repair, decreased heart rate variability, and increased awakening cortisol levels (19–23).

Identification of loci linked to depression has been elusive. Meta-analyses have found genetic linkage to neuroticism, a trait related to the onset of depression, and other studies have suggested linkage to genes involving glutamatergic neurotransmission, the hypothalamic–pituitary–adrenal (HPA) axis, and neural structure (24).

The most commonly reported candidate gene associated with depression is the less functional, short allele of the serotonin transporter gene, which has been reported to interact with stressful life events to result in an increased risk for depression (25). The consistency of this finding has been questioned (26), although it has been linked to a number of potential intermediate phenotypes for depression, such as hypersecretion of cortisol in response to a social stressor (27), increased amygdala reactivity to emotional faces (28), and negative cognitive bias (22).

Familial/Environmental Risk and Protective Factors

Twin studies show that the effect of shared environment is nearly as potent as are

heritable factors (19). In the ROOTS study conducted in the United Kingdom, parent–child interactions characterized either by maltreatment or discord were most consistently associated with increased risk for depression (12). Parental depression, particularly if chronic, may exert its deleterious effect on child mood disorder not only through genetic mechanisms, but also via modeling of cognitive distortions, and through either passive and withdrawn, or discordant parent–child interactions (29–32). Longitudinal studies show reciprocal interrelationships between maternal and child interpersonal difficulties, child behavior symptoms, cognitive distortions, and depressive outcome (29–32). Treatment of maternal depression results in prevention of onset, and reduction in child symptomatology (33).

Neglect and child maltreatment not only increases the risk for depression, but also for comorbid conditions (e.g., substance abuse), an earlier age of onset, more chronic and persistent depression, and greater likelihood of treatment nonresponse (34–36). The impact of maltreatment may be mediated through its impact on the inflammatory system, and via alterations in brain structure and brain function related to emotion regulation and reward response (37,38).

Bereavement due to the loss of a sibling, parent, or close friend is associated with an increased risk for depression (39,40). The negative impact of parental bereavement on youth depression is mediated by the functioning of the surviving parent and the adaptiveness of the child's coping style and may be more deleterious in the case of maternal loss (40). Bereavement is no longer an exclusion for the diagnosis of depression, consistent with findings that the risk factors, phenomenology, and course of depression are similar regardless of bereavement history (41).

Those who are bullied, as well as the bulliers show an increased risk for depression, possibly mediated by increases in negative cognitions about self, as well as an exaggerated cortisol response to social stress (42–44). Sexual minority youth have about a threefold increased risk for depression, explained in part by contributions due to parent–child conflict, parental rejection, peer victimization, and maltreatment (45,46).

Connection to family, friends, and to school, parental behavioral and academic expectations, and nondeviant peer group are all protective against depression, as well as health-risk behaviors (47,48).

Cognitive Bias

Depressed individuals have been shown to have a negative view of self, future, and the world, and these biases predict the onset and growth of depressive symptoms, particularly in the face of stressful life events (29,30,49). Both the presence and growth of depressive symptoms are associated with performance-based tasks that show evidence of cognitive bias, including bias toward negative emotional stimuli,

cognitive disruption in the face of emotional stimuli, and difficulty with inhibition of negative affect (22,50–53). Rumination, a cognitive style that involves preoccupation with emotionally upsetting thoughts and events, is a predictor of the onset and growth of depressive symptomatology, particularly in girls (30).

Mood Repair

Mood repair, or emotion regulation, is the ability to moderate extremes in emotional responses, and is posited to be a core ingredient in vulnerability to depression (54,55). Laboratory assessment of mood repair, including assessment of persistence in the face of frustration, and altered heart rate variability and respiratory sinus arrhythmia, has been shown to be related to the onset and growth of depressive symptomatology (54,55). Moreover, those with atypical respiratory sinus arrhythmia show greater difficulty in learning how to repair mood in a laboratory setting (55).

Sleep

Subjective sleep complaints are a very prominent component of early-onset depression, although subjective complaints and objective observations of sleep in a sleep laboratory are not closely correlated (56). The most consistent sleep laboratory finding associated with depressive onset, persistence, and recurrence is increased sleep latency (57). Insomnia has been found to have a stronger relationship with onset and growth of depressive symptoms than vice versa (58), perhaps explained by the impact of insomnia on attention to negative emotional stimuli, mood lability, and response to reward (59–61).

Anxiety

Behavioral inhibition and anxiety disorders pose an increased risk for depression, in part due to a shared genetic diathesis (19,62,63). The link between behavioral inhibition and latter depression may be mediated through the development of social anxiety (62). Consistent with this, cognitive bias *away* from negative emotional stimuli (e.g., avoidance) has been shown to predict growth of depressive symptomatology in anxious youth (64).

Externalizing Disorders and Irritability

Depression is a frequent outcome in youth with ADHD, perhaps due to peer and adult criticism and social rejection, and in part due to poor emotional regulation (65). ODD and conduct disorders are also associated with an increased risk of depression, mediated by negative affect and lability in ODD (66) and via irritability in those with

conduct disorder, respectively (67).

Medical Illness

Illnesses that involve the central nervous system (e.g., epilepsy, migraine) or that involve systemic inflammation (e.g., asthma, inflammatory bowel disease) as well some of the treatments for chronic illness (e.g., steroids, interferon) increase the risk for depression in youth (68–71). In addition to systemic effects of chronic illness, medical illness may predispose to depression by interfering with the youth's ability to engage in behaviors that promote positive mood.

Cortisol

A *blunted* response to social threat and low waking cortisol have found to be associated with depression in prepubertal samples (72,73), while *increased* morning cortisol has been associated with depression onset in postpubertal samples (72). High morning cortisol has been reported to be predictive of onset of depression in boys, but not girls, and in other studies, this relationship is qualified by past adversity, and current stressful life events (74–76).

Inflammation

There is growing evidence of involvement of inflammatory processes in youth depression, although the relationship between levels of inflammatory cytokines and depressive symptoms in some cases has been reported to be bidirectional (77). Inflammatory processes may partially mediate the relationship between adversity and depression (78), and may play a role in depression via its potential neurotoxicity and interference with central serotonin metabolism (37,77).

Neuroimaging Studies

Structural and functional neuroimaging studies are consistent with self-report and performance task studies of youth at risk for depression as well as those with depressive disorders, with alterations in structures and circuits that result in deploying greater attention to negative emotional cues, decreased ability to use prefrontal cortical mechanisms to inhibit subcortical activation to negative emotional cues, and impaired ability to anticipate, and experience positive affect and reward (79,80). Structural imaging studies of adult subjects with early onset, familial depression as well as in adolescents with depression have found reduced volume of the left subgenual prefrontal cortex and orbital prefrontal cortex (OFC) (81–83). Smaller hippocampal volume has been posited to be a risk for early-onset

depression, particularly if there is a history of maltreatment (84).

Functional magnetic resonance imaging (fMRI) studies find that depressed youth show greater activation in the amygdala, dorsal anterior cingulate, and insula in response to negative emotional stimuli, with *decreased* reactivity in the dorsolateral prefrontal cortex (DLPFC) on these same tasks (79,80). Studies of resting-state connectivity are consistent with these findings, showing *decreased* connectivity between the amygdala and DLPFC (79). Diffusion tensor imaging (DTI) studies have found decreased fractional anisotropy in the uncinate fasciculus, which connects the subgenual anterior cingulate cortex (ACC) and the ventromedial PFC (85,86).

Low positive affect is a risk factor for early-onset depression (87). Depressed adolescents and those at high risk for depression show a blunted response in the striatum, caudate, ACC, and orbitofrontal cortex during reward anticipation and receipt (80,88,89). The above-noted neural correlates of reward anticipation and response in adolescents at high risk for depression appear to be moderated by parent–child warmth, parental depression, parent–child conflict, and exposure to early adversity (87,90).

COURSE AND OUTCOME

Episode Length and Recovery

The duration for depressive episodes ranges between 3 and 6 months for community samples, and between 5 and 8 months for clinically referred samples (91). Factors associated with a longer episode duration include previous chronicity, comorbidity with anxiety disorder or substance abuse, greater initial severity of the depressive condition, current or past suicidal ideation or behavior, chronicity and number of episodes of parental depression, and family discord (91). In both clinical and community samples, around 20% of adolescents have a persistent depression of 2 or more years' duration (91).

Risk for Recurrence

In one study of the course of depressive disorder in children aged 8 to 13 years, the risk of recurrence was 40% in 2 years, and 72% in 5 years (91). Other longitudinal studies in treated samples have shown that the risk for relapse or recurrent depression in adolescent depression is between 30% and 70% in 1 to 2 years of follow-up (91–93). Risk factors for persistence and recurrence include parental depression, family discord, history of maltreatment, and comorbidity (36,91).

Risk for Bipolar Disorder

The risk for bipolar disorder in early-onset depression is estimated to be around 10% to 20%, and is higher in patients who present with a history of antidepressant-induced or spontaneous hypomania, psychotic features, hypersomnia, and a family history of bipolar disorder (94). Depressed children and younger adolescents exposed to antidepressants may be at particularly high risk for manic switch (95).

Other Sequelae

Depressed youth are at increased risk for suicidal behavior, impairments in interpersonal, educational, and occupational functioning, as well as increased risk for obesity and cardiovascular disease (96–99). Poor functioning can be a sequelae of depression as well as an indicator of incomplete recovery (99), but comorbidity with alcohol, tobacco, and cannabis use is more likely to be due to the impact of substance use on mood than vice versa (7–9).

CLINICAL MANAGEMENT

There are currently three well-established evidence-based treatments for adolescent depression, namely, antidepressant treatment, cognitive behavior therapy (CBT), and interpersonal therapy (IPT) (100). There has been considerably less research on treatment of prepubertal children with depression, although there is some support for the efficacy of antidepressants. Each of these three approaches will be discussed, followed by a recommendation for current "best practice" treatment of youth depression.

Antidepressant Medication

Evidence of Efficacy

Both the single largest placebo-controlled comparison study of tricyclic antidepressants (TCAs) and placebo, and a subsequent meta-analysis showed no difference between TCAs and placebo (101,102), while several studies have demonstrated efficacy with selective serotonin reuptake inhibitor (SSRI) antidepressants (103). A meta-analysis of both published and unpublished available clinical trials, shows that SSRIs are superior to placebo, with the average response rate for antidepressant versus placebo of 60% versus 49%, for an overall Number Need to Treat (NNT) of 9 (103). A higher risk difference between drug and placebo was found in studies with fewer sites, and those that selected participants with greater global severity (104).

Fluoxetine is the best-studied antidepressant with the strongest efficacy data, and consequently is the only antidepressant to receive FDA and MHRA approval for use

for the treatment of depression in both children and adolescents, with an NNT = 5 (103). In the Treatment of Adolescent Depression Study (TADS), fluoxetine was more efficacious than placebo after 12 weeks of treatment (proportion "much or very much" improved, 61% vs. 35%, respectively) (105). The impact of escitalopram, sertraline, and venlafaxine on pediatric depression is more modest, with stronger effects in adolescents (103,106,107). Paroxetine is not superior to placebo for adolescent depression, and so this agent is not recommended in this age group (103,108).

Adverse Events in Antidepressant Treatment

The FDA conducted a meta-analysis that found a higher rate of suicide-related, spontaneously reported adverse events on drug than on placebo (4% vs. 2%) (109). There were relatively few suicide attempts and no completions. A more recent meta-analysis that included additional studies and using random rather than fixed effects models reported a risk difference for suicidal adverse events between drug and placebo of 0.9% (103). Between 4.5 and 11 times more youth will respond to an antidepressant than will experience a suicidal event (103,108). Suicidal events are most common in the first 4 weeks of treatment and are more likely to occur in those who enter clinical trials with suicidal ideation, a history of nonsuicidal self-injury, substance use, family conflict, and who do not respond to antidepressant treatment (110).

Meta-analyses have also found that antidepressant-treated youth have about twice the incidence of hostility and aggression and a much higher incidence of mania compared to those treated with placebo (for the latter, 10% vs. 0.5%) (111,112), with the risk greatest of mania in those under the age of 14 (95). In addition, antidepressants are associated with increased incidence of sleep disruption, vivid dreams, nausea and gastrointestinal distress, agitation, akathisia, anxiety, headache, serotonin syndrome (particularly in combination with other serotonergic agents) and bruising (due to a prolongation of clotting time) (113). The latter side effect is usually not clinically significant, but can become so in patients with intrinsic coagulation disorders or who are undergoing surgery.

Predictors of Antidepressant Response

Clinical severity, comorbidity, insomnia, and family conflict predict a poorer response to antidepressants (114–116). Lower drug concentration, nonadherence, anhedonia, and sub-syndromal manic symptoms have also been reported to be associated with antidepressant nonresponse (117–120).

Cognitive Behavior Therapy

Theory and Techniques

CBT is predicated on the observation that depressed individuals show biases in their thinking and information processing, preferentially attending to negative emotional stimuli that reinforce a depressed mood (29), especially during times of stress (49). CBT treatments for depression focus on interrupting this cycle of negative thinking, mood, and maladaptive action, through a variety of cognitive techniques and behavioral skill-building exercises. Central to the treatment model is *cognitive restructuring*—an effort to make the patient aware of negative distortions and to teach the individual how to counteract them, thus relieving depression as a result. The cognitive theory of depression has been supported by studies of performance-based tasks and fMRI studies. fMRI studies show impaired top-down cognitive control of emotion response, and CBT aims to strengthen the ability of the patient to deploy prefrontal cortical resources through cognitive restructuring (80,121).

Also key to the application of CBT is the use of *behavioral activation* (BA) techniques, that is, encouraging patients to normalize their routine and engage in rewarding activities, even if they do not feel like it at the time. BA is based on the observation that depressed individuals tend to withdraw from activities that are potentially reinforcing, but that if coaxed to participate, can experience those activities as rewarding. Preliminary evidence shows that BA approaches can increase activation in reward-related circuitry and that this change appears to mediate improvement in depressive symptoms (122).

While these two techniques appear to be core to the theory and practice of CBT, the content of CBT treatment manuals tested in clinical trials varies greatly in the emphasis on each of these techniques and the inclusion of other, adjunctive skill-building elements (e.g., problem solving, relaxation, emotion regulation, assertiveness training). In addition, CBT approaches are heterogeneous with regard to the overall number of sessions, the number of sessions devoted to each CBT technique, degree of structure, and therapy format (group or individual), differences that make it difficult to interpret the varying effects of CBT reported across clinical trials.

In Acute Treatment, Efficacy of CBT

CBT has been shown to be more efficacious than supportive, relaxation, and one form of family therapy. However in longer-term follow-up, the outcomes of CBT and these other types of therapy converged (123,124). CBT has been shown to be more efficacious than other forms of treatment in reducing cognitive distortions, and also appears to work by improvement in problem-solving ability (125,126). Internet versions of CBT has been shown to be efficacious for adolescents and young adults, including one version of game-based CBT (NNT = 3) (127,128).

The most comprehensive clinical efficacy trial in adolescent depression is the

TADS study (105), which compared CBT, fluoxetine, their combination, and placebo in 439 depressed adolescent patients. After 12 weeks of treatment, CBT (43% significantly improved) was not superior to placebo (35%), and whereas both fluoxetine monotherapy (61%) and the combination of fluoxetine and CBT (71%) were superior to placebo (105). By 18 weeks, CBT has similar outcomes to the other two active treatments (129). CBT may not have shown as vigorous a response in the TADS trial as in other studies because the manual contained many different techniques that were all offered to patients at a low "dose" (130).

Predictors of Outcome

Naturalistic data suggest that an adequate response requires at least nine sessions, and that active ingredients include social skills training and problem solving (131). CBT, either alone, or in combination with medication appears to be particularly efficacious for those with high levels of cognitive distortions and comorbidity, whereas in the presence of parental depression or history of maltreatment, CBT is not better, and sometimes worse than alternative treatments (115,116,132). When CBT management of insomnia was added to CBT treatment for depression, the long-term outcome for remission of depression was superior to that achieved by CBT for depression alone (133).

Combined CBT and Medication

In the TADS study, the combination of CBT and fluoxetine was similar to fluoxetine alone with regard to initial response rates, but combination had a higher remission rate, showed superior adaptive functioning, and evoked faster declines in self-reported depression and suicidal ideation (105,134). In TADS, fewer suicidal events were found in those treated with combination relative to fluoxetine alone (129), although other studies of combined CBT and antidepressant medication did not find a protective benefit on suicidal outcomes compared to medication monotherapy (135,136). Clarke et al. (137) studied the addition of CBT to antidepressant management in primary care. This combined treatment resulted in some modest improvement in quality of life, but improvement in depressive symptoms never reached statistical significance; moreover, patients in the combined treatment were more likely to stop their antidepressants or receive a reduced dose. A second study, the Adolescent Depression Antidepressant and Psychotherapy Trial (ADAPT), conducted an open run-in of brief supportive therapy and randomized nonresponders to this brief intervention to either fluoxetine monotherapy, or the combination of CBT and fluoxetine (135). CBT did not add to medication alone with regard to global functioning, quality of life, or depressive symptomatology, although this sample was probably the most severe and complex of any of the large clinical trials.

INTERPERSONAL THERAPY

Theory and Techniques

IPT for adolescents (IPT-A) is an adaptation of IPT, a well-established, efficacious treatment for adult unipolar depression (138). In this treatment, depression is conceptualized as occurring within an interpersonal matrix and IPT-A targets resolution of interpersonal stress that seems to be associated with the adolescent's depression. IPT-A begins by taking an interpersonal inventory of important relationships in order to determine appropriate treatment targets. The types of problems typically targeted by IPT-A are loss, role disputes, role transitions, interpersonal skills deficits, or adjustment to a single-parent family. The goal of treatment is to replace conflictual, unfulfilling relationships with those that are more meaningful, rewarding, and less conflictual.

The IPT formulation and set of techniques are not fundamentally incompatible with the cognitive view of depression. In fact, there are several similarities, including education about depression as an illness, encouragement of the individual to resume normal activities, problem solving, and skill building. However, IPT tends to look from the outside in, whereas, CBT tends to look at inner experience and how it relates to the interpersonal. IPT-A is a very developmentally appropriate treatment, since adolescence is a time of role changes, conflicts with parents, and the investment of more emotional capital in peer relationships.

Evidence of IPT Efficacy

Mufson et al. (138) conducted the first efficacy trial of IPT-A in a patient population of depressed adolescents. Forty-eight adolescents were randomized to either IPT-A or monthly clinical management. A much higher proportion of adolescents met recovery criteria (Hamilton Depression Scale-Depression ≤6) in the IPT-A group (75% vs. 46%, NNT = 4). Analyses of dimensional measures of depressive symptomatology, functional status, and social adaptiveness also favored IPT-A. Two clinical trials compared CBT and IPT for depressed Puerto Rican adolescents, with one study finding IPT superior to CBT, and other finding CBT superior to IPT (139,140). In one of the few clinical psychotherapy trials for prepubertal depressed youth, an adaptation of IPT, termed family-based IPT (FB-IPT) was tested against supportive psychotherapy (141). FB-IPT was superior to supportive therapy in achievement of remission (66% vs. 31%), and in the reduction in social impairment, with the latter mediating FB-IPT's impact on depressive symptoms (141).

Predictors and Moderators of Response

IPT-A is particularly efficacious in youth with greater depressive severity, comorbid

anxiety, poorer interpersonal functioning, high levels of conflict with parents, and a greater cortisol response to a lab-based assessment of parent–child conflict (138,142–144).

TREATMENT, PREVENTION, AND EFFICACY

Treatment-Resistant Depression

Treatment-resistant depression is defined as the persistence of depression after having received adequate quality and dose of an evidence-based treatment. The Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) study was designed to determine what clinicians should do next after a patient does not respond to an adequate trial with an SSRI (107). In TORDIA, 334 adolescents were randomized to a switch to another SSRI, switch to venlafaxine, switch to another SSRI plus CBT, or switch to venlafaxine plus CBT. After 12 weeks, the addition of CBT to either medication strategy resulted in a superior outcome to medication monotherapy, and the effects of the SSRI and venlafaxine interventions were similar, except that venlafaxine resulted in more side effects.

Prevention of Relapse

In depressed adolescents who have responded to fluoxetine treatment, continued treatment with fluoxetine is much superior to placebo in preventing depressive relapses (92). The addition of 12 sessions of a wellness-based CBT to continuation pharmacotherapy decreased the relapse rate even further (93).

Effectiveness

In one test of the effectiveness of evidence-based CBT treatment, community therapists were randomized to training and supervision in CBT versus usual care for adolescent depression (145). CBT was not superior to usual care, but accomplished its results in significantly fewer sessions and involved fewer other services, resulting in a lower net cost for similar therapeutic outcomes. Another approach designed to make evidence-based treatments more effective is modular treatment, which employs an algorithm for prioritizing and sequencing different types of evidence-based treatments, whereas “regular” evidence-based care allowed for clinician discretion in the selection, prioritization, and sequencing of manual-based treatments. In one clinical trial that treated several conditions, including depression, modular treatment was superior to manualized care and usual care, and manualized care and usual care were not different from one another (146). Mufson et al. (147) tested the effectiveness of IPT-A versus usual care in school-based mental health clinics. School social workers delivered both interventions, after a brief training in IPT-A

and weekly supervision. IPT-A was superior to usual care on dimensional measures of depression, global function, social adjustment, and global clinical status (50% vs. 33% symptomatically improved). Studies have examined the transportability of CBT and antidepressant treatment into primary care settings, and shown that evidence-based primary care interventions are dramatically superior to usual care, both for depression and other conditions as well (148,149).

Prevention

The impact of Coping with Depression for Adolescents (CWD-A) on the prevention of depressive onset or recurrence in youth who are the offspring of depressed parents was tested in a 4-site study. CWD-A significantly reduced the onset of depressive disorders relative to treatment as usual at 9 months after the intervention (depression onset of 21.4% vs. 32.7%, NNT = 9) (150). If one of the parents was currently depressed during the intervention, the CWD-A was no better than usual care (150). The positive effects of the program on depression outcomes and adult functioning were present 75 months after the intervention, with the effects of the intervention on adult functioning mediated by the number of depression-free days, illustrating the importance of relief of depression at this critical stage of development (151). Both universal and indicated preventive interventions have been shown to be efficacious, although indicated interventions have larger effects (152). A family CBT intervention has been found to be efficacious in the reduction of depressive onsets in the offspring of depressed parents, with the effects mediated by changes in youth coping, and parenting behavior (153,154). A modification of IPT-A delivered in a group format that included adolescent skills training (IPT-AST) was compared to supportive counseling in a school setting, and IPT-AST showed a greater decrease in levels of depressive symptomatology and improvement in functioning (155). One study compared IPT-AST, CBT, and a no-treatment group, and found that both active conditions were superior to no-treatment on reduction in depression, with stronger effects in those with higher levels of depressive symptomatology (156).

Other Available Interventions

One promising treatment that is currently being evaluated in a large clinical trial, attachment-based family therapy (ABFT), has been found to be superior to clinical management in the reduction of depression and suicidal ideation in two clinical trials of largely impoverished and minority youth (157,158). With regard to somatic treatments, 1 hour of light therapy in the morning has been shown to be beneficial for pediatric seasonal affective disorder, and may be beneficial for treatment of mild depression and as an augmentation of pharmacotherapy of depression (159–161).

Recommendations for Current Best Practice Treatment

Since there is a relatively high response rate to placebo or brief supportive treatment and education in many of the published treatment studies, the first approach for mild depression should be family education, supportive counseling, case management, and problem solving. For more persistent, moderate depression, one of the three empirically validated treatments, SSRI medication, CBT, or IPT, is indicated. Initial treatment with any of the three treatments for moderate depression is reasonable, with the choice informed primarily by patient preference and the availability of local expertise. If the patient does not show any improvement after 6 to 8 weeks, consideration should be given to a change of treatment (e.g., psychotherapy to medication or vice versa), or augmentation (adding psychotherapy to medication or vice versa). In many communities, there is a paucity of clinicians trained in CBT or IPT-A, and the evidence suggests that more generic psychotherapies practiced in the community may not be helpful in the treatment of youth depression (123,162). In the absence of available specialized psychotherapy, or in the face of a patient's disinclination to engage in psychotherapy, use of an antidepressant as a first-line intervention is indicated. Patients should be seen or evaluated by phone weekly for the first 4 weeks of antidepressant treatment or after a dose adjustment in order to monitor for adverse effects of antidepressants such as suicidality, hostility, and mania.

For more severely depressed adolescents, particularly those with difficulties with motivation, concentration, sleep, and appetite, medication should be a first-line treatment. The combination of CBT and antidepressant results in a more rapid improvement, and is more effective than medication monotherapy for first onset, and for chronic, treatment-resistant depression (105,107). Relative contraindications for use of antidepressant medication are a history of mania or hypomania, for whom mood stabilization should be undertaken prior to the use of antidepressants, and for those with a strong family history of bipolar disorder, for whom it may be safer to begin with psychotherapy for the same reason.

Given that the most and strongest evidence for efficacy exists for fluoxetine, this should be the first-line medication. For those who have failed to respond to fluoxetine, cannot tolerate it, or for some reason do not wish to take it, use of one of the other SSRIs for which there is some evidence of efficacy is warranted, such escitalopram or sertraline. Current clinical recommendations are to begin with half the usual initial target dose (e.g., the equivalent of 10 mg fluoxetine) for 1 week, to determine if the patient can tolerate the medication, and then increase to 20 mg for the next 3 weeks. If the patient does not respond to 20 mg and is tolerating the medication, it is reasonable to increase the dosage to 40 mg, in light of previous studies (120). Further dose increases would be indicated if there is evidence of rapid metabolism, or if the patient has comorbid obsessive compulsive disorder or anxiety

disorders, for which higher doses of SSRIs may be useful (163). If a patient fails to respond to a fluoxetine at an adequate dose and duration then, based on the TORDIA study, patients should be switched to another SSRI and in addition should receive CBT (107). However, it is important to rule out reasons for continued depression such as rapid drug metabolism, nonadherence, presence of undiagnosed medical or psychiatric comorbidity (e.g., insomnia, psychosis, cannabis abuse, bipolar disorder), or environment stressors, such as family conflict, parental depression, peer victimization, or same-sex attraction. Expert consensus recommends that if a patient shows partial response to an agent, then augmentation should be considered, and while empirical studies in youth are lacking, adult studies support augmentation with lithium, bupropion, and antipsychotics among other agents (100). After nonresponse to a second SSRI, one should consider switching to an antidepressant of a different class. If the patient has prominent anxiety, then a selective norepinephrine/serotonin reuptake inhibitor is a logical next step. If a patient has low motivation and fatigue, or comorbid ADHD, then bupropion might be a logical next step. After treatment nonresponse to three antidepressants, patients should be considered for ECT, with naturalistic studies indicating best outcomes in those with psychosis or mania, and less favorable outcomes in those with personality disorder (164).

Treatment should focus on achievement of remission, because residual symptoms of depression can increase the likelihood of depressive relapse (2). Moreover, if a patient has achieved symptomatic remission, he or she should continue on the same regimen for at least 6 months before considering withdrawal of medication (92). Addition of CBT to continuation medication treatment can increase the likelihood of staying well (93). Patients with more severe and chronic disorder, or who are about to embark on potentially stressful transition, for example, a year abroad, should receive continuation treatment for longer periods of time.

FUTURE CHALLENGES

1. *Improving access to care for child and adolescents with depression* . Since the black box warning about the risk of suicidal events associated with use of antidepressants in adolescents and young adults, there has been a decline in the use of antidepressants in adolescents and even a decline in the rendering of a depressive diagnosis in adolescents (165). Collaborative care, that is the colocation of mental health specialists in pediatric and family medicine primary care, has been shown to improve access to care and outcome in depression, and in overall mental health issues (148,149). The dissemination of evidence-based treatments that can be delivered with less intense clinician involvement, such as via the Internet can also help to improve access to evidence-based care (166).
2. *Deconstruction of depressive disorders into dimensions that can be reliably*

assessed and can be linked to neural mechanisms that can be targeted with effective treatments. The Research Diagnostic Criteria (RDoC) initiative aims to deconstruct current nosologically heterogeneous entities such as depression into biologically coherent sub-groups that then frame appropriate treatment targets and mechanisms (167). For example, anhedonia is a dimension associated with depression as well as with other psychiatric conditions that has a unique neurocircuitry and may respond to specific types of interventions such as BA, as compared to cognitive therapy (122).

3. *Improved understanding of the contribution of early and current adversity to the pathogenesis of early onset and treatment.* Maltreatment accounts for a very high proportion of the population attributable risk of early-onset depression, and also greatly increases the likelihood of nonresponse to treatment (36). Research is indicated to identify the neurobiologic basis of the more extreme clinical phenotype of depression associated with early and current adversity, and the translation of those findings into interventions that are more effective than our current interventions for this important sub-population of depressed individuals (38).
4. *Translation of the explosion in our understanding of the neurocircuitry of depressive disorders into improvements in interventions.* Currently, our ability to identify neural abnormalities associated with depression greatly outstrip our ability to translate those findings into viable interventions. Novel approaches that target neural circuitry may be useful as research probes and therapeutic interventions (168).
5. *Metabolomic approaches to treatment-resistant depression may help shed light in improving outcome in youth and adults with chronic, treatment-resistant depression.* Promising research into the etiology and treatment of chronic, resistant depression has identified that a surprisingly high proportion of treatment-resistant depressed patients may have one or more metabolic abnormalities, such as cerebral folate deficiency, that may in turn respond to replacement treatment (e.g., folinic acid) (169).
6. *Prevention of cardio-metabolic disorders in depressed youth.* Depressed youth have greatly increased risk of cardio-metabolic disease (170), and share risk factors for these physical conditions such as inflammation and reduced heart rate variability (21,77). Interventions to target these shared risk factors might greatly improve mortality and morbidity in depressed youth.

CHAPTER 5.4.2 ■ BIPOLAR SPECTRUM DISORDERS

BORIS BIRMAHER, TINA GOLDSTEIN, DAVID A. AXELSON, AND MANI PAVULURI

INTRODUCTION

Consistent with Kraepelin's early descriptions (1921) (1), it is now recognized that bipolar disorder (BP) occurs in children and adolescents. This disorder severely affects the normal development and psychosocial functioning of the child and is associated with increased risk for suicide, psychosis, sexual risk behaviors, substance abuse, as well as for behavioral, academic, social, and legal problems. However, many youth do not receive treatment, and of those who do, many receive treatment for comorbid conditions rather than for their mood condition (2). Moreover, it takes an average of 10 years to identify and begin treatment of BP (3), and the longer it takes to start appropriate treatment, the worse the adult outcomes.

TABLE 5.4.2.1

DSM-5 CRITERIA FOR A MANIC EPISODE

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and persistent increase in goal-directed activity or energy for at least 1 wk and present most of the day, nearly every day (or any duration if hospitalization is necessary).

B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent noticeable change from usual behavior:
1) Inflated self-esteem or grandiosity
2) Decreased need for sleep (e.g., feels rested after only 3 hrs of sleep)
3) More talkative than usual or pressure to keep talking
4) Flight of ideas or subjective experience that thoughts are racing
5) Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli)
6) Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (e.g., purposeless nongoal-directed activity)
7) Excessive involvement in pleasurable activities that have a high potential for painful consequences (engaging in unrestrained buying sprees, sexual indiscretions)

C. The mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or in usual social activities or relationships with others, or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

D. The symptoms are not due to the direct physiological effects of a substance (a drug of abuse, a medication, or other treatment) or to another medical condition.

Note: A full manic episode that emerges during antidepressant treatment (medication, electroconvulsive therapy, light therapy), but persists at a fully syndromal level; beyond the physiological effect of that treatment is sufficient evidence for a manic episode and therefore, a bipolar I diagnosis.
Criteria A to D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

The goal of this chapter is to review the clinical picture, epidemiology,

differential diagnosis, course and prognosis, risk factors, and pharmacologic and psychosocial treatment of pediatric BP. For the purposes of this chapter, the word *youth,* unless specified, denotes children and adolescents. To date, all studies in pediatric BP employed Diagnostic and Statistical Manual of Mental Disorders-IV (DSM-IV) criteria (4). However, with some exceptions (e.g., adding increased goal-directed activity or high energy to elevated or irritable mood to the criterion A and modification of "mixed" from episode to specifier), the DSM-5 (5) diagnostic criteria for mania and hypomania are similar to the DSM-IV (for the DSM-5 criteria, see Tables 5.4.2.1 and 5.4.2.2).

CLINICAL CHARACTERISTICS

Most clinicians acknowledge that pediatric BP exists, and that the symptoms of pediatric BP are similar to those in adults when accounting for the effects of psychosocial development. However, there is debate on the following issues regarding the phenomenology of pediatric BP: (1) the necessity of cardinal or key symptoms (e.g., elated mood and/or grandiosity) for a BP diagnosis; (2) the role of irritable mood in pediatric BP; (3) the requirement of clearly demarcated mood episodes; (4) the temporal relation between manic and depressive symptoms and mood cycling patterns; (5) the validity and importance of manic symptoms that do not meet the DSM symptom requirements or duration thresholds for a manic, hypomanic, or mixed episode; and (6) the best way to attribute potential symptoms of mania that also commonly present in other pediatric psychiatric disorders. Though the issue of diagnostic features of BP in youth has provoked considerable controversy, it is important to note that many of these issues similarly remain unclear in the adult BP literature. Thus, the conceptualization of BP will continue to evolve as more research becomes available.

TABLE 5.4.2.2

DSM-5 CRITERIA FOR A HYPOMANIC EPISODE

A. A distinct period of persistently elevated, expansive, or irritable mood and persistent increase in goal-directed activity or energy lasting at least 4 consecutive days and present most of the day, nearly every day.
B. Same as B criterion for manic episode.
C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the person when not symptomatic.
D. The disturbance in mood and the change in functioning are observable by others.
E. The episode is not severe enough to cause marked impairment in social or occupational functioning, or to necessitate hospitalization, and there are no psychotic features.
F. The episode is not attributable to the physiological effects of a substance (a drug of abuse, a medication, or other treatment) or a medical condition.

Note: A full hypomanic episode that emerges during antidepressant treatment (medication, electroconvulsive therapy, light therapy), but persists at a fully syndromal level; beyond the physiological effect of that treatment is sufficient evidence for a hypomanic episode. However, *caution*

is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for the diagnosis of a hypomanic episode, nor necessarily indicative of a bipolar diathesis.
Criteria A to D constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Applying the DSM Criteria

It is clear from the work of several groups that some youth meet the full DSM-IV criteria for BP, despite the fact that the criteria were not specifically developed for use in the pediatric population (1,6–9). When examining the DSM criteria for a manic or hypomanic episode, it is obvious that normal youth can exhibit some manic or hypomanic symptoms to some degree, especially in certain situations or environments. Thus, it is of utmost importance to evaluate whether the mood and symptoms are abnormal, clearly different from the youth's usual mood and behavior, above and beyond the youth's developmental level and the context where the symptoms occur, and the extent to which the symptoms affect the functioning of the youth. For instance, elevated mood, high activity level, and rapid speech would not be considered evidence of mania in a 7-year-old at a birthday party or among a group of adolescents at an amusement park.

Consideration of how manic symptoms may manifest differently across development can facilitate accurate diagnosis. For instance, in contrast with an adult who is in a manic episode, a school-age child is not likely to exhibit behaviors such as engaging in risky business ventures, driving recklessly, going on spending sprees, or having sexual relations with multiple partners. However, they can exhibit inappropriate sexual behavior (touching others inappropriately, frequent public masturbation, or drawing sexually provocative pictures) or engage in uncharacteristically dangerous, risk-taking play such as jumping from high places or performing frequent and exaggerated daredevil stunts on a bicycle (6,8).

The distinction between a manic and hypomanic episode can be challenging, but also must be taken in a developmental context. Beyond the differences in minimum duration, manic episodes require marked impairment, which should be measured against the expected level of functioning for a youth given his/her chronologic age and intellectual capabilities. Functioning should be examined across the psychosocial domains that are relevant to youth (school, family, peers). A hypomanic episode also requires impairment, but some youth may function better while hypomanic. For any type of episode, there must be an unequivocal positive or negative change from usual functioning, and the mood and functional changes must be observable by others. Given that lack of insight can be associated with mania or hypomania and that the diagnosis of pediatric BP is more accurate when parents are the reporters (see Assessment section below), it is imperative to obtain information from caregivers or other significant adults in the youth's life in order to accurately assess symptoms and

potential change in functioning.

Symptoms of Mania

A recent meta-analysis of 20 published studies (*N* = 2,226) evaluated the weighted rates of manic symptoms in youth (average age: 11.5 years old, 64% male, mainly Caucasian) with BP-I and BP not otherwise specified (BP-NOS) (7). As shown in Table 5.4.2.3, the most common symptoms across BP subtypes included increased energy, irritability and mood lability, distractibility, and goal-directed activity (all approximately 75%), while hypersexuality, hallucinations, and delusions were the least frequent (all approximately 26%). Grandiosity and hypersexuality were the most specific symptoms, but they were less common (57% and 32%, respectively). As expected, youth with BP-I had more severe and greater number of symptoms than those with BP-NOS. As depicted in Figure 5.4.2.1, there was significant variability in the rates of many symptoms, particularly in youth with BP-NOS, and with few exceptions, the variability was not accounted for by the year of data collection, age, sex, study quality, and methodologic approach utilized in the study (e.g., informant, diagnostic instrument). Other variables not measured, such as the timing of data collection with respect to the time of the acute episode, and how the studies measured and conceptualized symptoms (e.g., “double-counting” symptoms that are diagnostic for both mania and attention deficit hyperactivity disorder [ADHD]) may also have contributed to the variability. Though it is not a symptom of mania per se, psychosis frequently occurs in BP youth. In the meta-analyses, perhaps due to the complexity assessing psychosis in youth (particularly in children), the weighted rates of psychosis were unexpectedly high (31% hallucinations and 24% delusions), although there was significant heterogeneity among the studies.

TABLE 5.4.2.3

WEIGHTED AVERAGE PREVALENCE RATES FOR MANIC SYMPTOMS FOR YOUTH WITH BIPOLAR SPECTRUM DISORDERS (BP-I, BP-II, AND BP-NOS)

Symptom	Prevalence, %	95% Confidence Interval
Increased energy	79	61–93%
Irritability	77	71–92%
Mood lability	76	61–85%
Distractibility	74	69–90%
Irritability	81	55–94%
Grandiosity	78	67–85%
Racing thoughts	74	51–88%
Decreased need for sleep	72	53–86%
Euphoria/elation	70	45–87%
Poor judgment	69	38–89%
Flight of ideas	56	46–66%

Hypersexuality	38	31–45%

From Van Meter AR, Burke C, Kowatch RA, Findling RL, Youngstrom EA: Ten-year update meta-analysis of the clinical characteristics of pediatric mania and hypomania. *Bipolar Disord* 18(1):19–32, 2016.
FIGURE 5.4.2.1. Comparison of weekly symptom status (the percentage of follow-up weeks spent asymptomatic or symptomatic in different mood categories during a 2-year prospective follow-up) between youth with BP-I, II and NOS. BP, bipolar disorder; NOS, not otherwise specified. (From Birmaher B, Axelson D, Strober M, et al.: Clinical course of children and adolescents with bipolar spectrum disorders. *Arch Gen Psychiatry* 63:175–183, 2006.)

One factor that may contribute to the difficulty diagnosing BP in youth is that the most common symptoms of pediatric mania identified in the meta-analysis are also frequently present in other pediatric psychiatric disorders. A recent study comparing the phenomenology of BP and ADHD found that there were no significant differences between the BP and the ADHD subjects in rates of irritability (98% BP vs. 72% ADHD), accelerated speech (97% vs. 82%), distractibility (94% vs. 96%), or unusual energy (100% vs. 95%) (10). Thus, the lack of specificity makes it problematic to diagnose mania by simply counting the presence or absence of symptoms.

Cardinal Symptoms

The overlap of manic symptoms with features of other psychiatric illnesses emphasizes the diagnostic importance of symptoms more specific to mania. Some authors have advocated that two of these manic symptoms, elated/elevated mood and grandiosity, are core features of the manic syndrome, so they should be considered

cardinal or hallmark symptoms (8–11). As shown in the meta-analysis noted above, these two symptoms are present in 64% and 57%, respectively, but there is considerable heterogeneity among studies.

Irritability in Pediatric Bipolar Disorder

Irritability has been defined as "... an emotional state characterized by having a low threshold for experiencing anger in response to negative emotional events" (12). Irritability can encompass multiple temporal features of abnormal emotional reactivity, including a lower threshold to anger, a faster increase in anger, a higher "peak" level of anger, and a longer duration of anger.

As noted above, irritability is present in nearly all manic children and adolescents, so it is a sensitive marker for pediatric BP. However it is also part of the DSM-IV diagnostic criteria for disorders such as disruptive, major depressive, generalized anxiety, and posttraumatic stress. In addition, it is frequently present in youth with other psychiatric diagnoses (e.g., ADHD, autism spectrum disorders [ASD]). Therefore irritability has low specificity for BP. The DSM-IV and the DSM-5 criteria for a manic episode explicitly allow for the presence of irritable mood alone to satisfy the "A" criterion, though it is qualified by the requirement of an additional symptom criterion. Some reports have prompted substantial controversy by stating that chronic presentations of irritability alone, particularly when the irritability is severe and accompanied by aggression and volatility, is the primary mood disturbance in BP youth and that elevated or expansive mood is uncommon (13–15). However, the high prevalence of elated/expansive mood in most cross-sectional pediatric BP samples stands in contrast to these reports. Moreover, a recent large study showed that only 10% of youth with BP had irritability or elation alone, whereas most of the sample had both symptoms at intake and during the follow-up (16,17).

Due to the controversy regarding irritability as a key symptom for the diagnosis of pediatric BP, the DSM-5 included a new disorder in the category of mood disorders entitled Disruptive Mood Dysregulation Disorder (DMDD). This disorder is characterized by frequent, severe, recurrent temper outbursts and chronically irritable and/or angry mood, both of which must be present for at least a year and cannot be accounted by other mood disorders. Since the key symptom for DMDD is irritability and this disorder is highly comorbid and sometimes indistinguishable from ODD, the same issues discussed above for irritability apply to DMDD (18–20).

Episodic Versus Chronic Mania

The DSM criteria for manic or hypomanic episode require a distinct period of abnormal mood and accompanying symptoms, and most authors have advocated that

an episodic course is a key feature for a definitive diagnosis of BP (6,9,11). Nevertheless, some groups assert that BP youth present with chronic manic symptoms, and have reported mean durations of 3 to 4 years for manic or mixed episodes (21,22). As noted below, BP youth have high rates of comorbid disorders, particularly ODD and ADHD, which manifest with nonepisodic and nonspecific symptoms of mania such as irritability, rapid speech, psychomotor agitation, and distractibility. This fact together with the rapid mood fluctuations and complex admixtures of manic and depressive symptoms found in BP youth can make it difficult to identify distinct episodes that are embedded in this “miscellaneous” presentation. However, a large prospective study of BP youth showed that close longitudinal clinical observation demonstrated that pediatric BP indeed is an episodic illness (23,24).

Depression

Depressive symptoms are noted to be prominent features in most phenomenologic studies of BP youth, and BP adults frequently recall having significant depressive symptoms in childhood or adolescence (3,6,25,26). BP youth can have clear periods of depression that meet the full criteria for a major depressive episode (MDE) and recurrent subsyndromal depressive symptoms (see Chapter 5.4.1 for the DSM criteria for MDE) (23). As described in the differential diagnosis section following, major depression may precede the onset of mania, so that some youth who appear to have unipolar depression may actually have BP with depression as their initial presentation. Mild or transient manic symptomatology that does not meet the diagnostic threshold for mania or hypomania may also precede an MDE, although the presentation of full DSM-IV/5 criteria for BP-II (MDE plus at least one hypomanic episode) does not appear to be common in youth with BP (6,23). All of these factors highlight the need to carefully probe for a history of threshold or subthreshold manic symptoms in youth presenting with depression.

Temporal Relation of Manic and Depressive Symptoms

Many researchers have reported that BP youth often present with mixed states and complex cycling patterns between depression and mania (23). Some groups have reported chronic mixed states lasting years in duration and rapid cycling between mania and depression as frequently as several times per day (13,27). However, it seems that these cycles do not represent new episodes, but mood fluctuations within the same episode. Moreover, the issue is complicated by the fact that there are no clear boundaries that delineate a mixed state from an actual switch in episode polarity, or from mood lability and/or transient dysphoria occurring in the midst of mania. The DSM-IV criteria for a mixed episode require that the criteria for both a

manic/hypomanic episode and an MDE be met; the DSM-5 criteria require depression with three manic symptoms or mania plus three depressive symptoms. This could be satisfied by an episode consisting of: (1) an amalgamation of manic and depressive symptoms that present concurrently (expansive, irritable, and depressed mood; high energy; racing thoughts; rapid speech; hopelessness; guilt; and suicidality); (2) cycling between distinct short periods of predominantly manic symptoms and predominantly depressive symptoms; or (3) some combination of both types of presentations. Overlapping criteria and features plus the symptoms of other comorbid psychiatric disorders can make it difficult to determine whether symptoms should be attributed to depression or mania. For example, irritability, racing thoughts, and psychomotor agitation can occur in both mood states and it can be challenging to differentiate decreased need for sleep from insomnia occurring in an agitated depression. Published studies have used patients' retrospective recall over long time intervals which limits reliable evaluation of symptom patterns. It is not clear whether the reports of multiple mood cycles in a day represent periods when the child switches from meeting the full criteria of the manic syndrome to periods when they are completely depressed, or whether they are manifestations of mood lability within the manic state. However, the evidence does indicate that the majority of BP youth have symptoms of depression interspersed in some manner with manic symptoms.

Subthreshold Presentations and Cyclothymic Disorder

Some children and adolescents present in clinical and research settings with what appears to be significant manic symptomatology, but do not meet full DSM-IV/5 criteria for BP-I or BP-II (6,28). These youth are frequently assigned the DSM-IV diagnosis of BP-NOS (in the DSM-5 "other specified or unspecified bipolar and other related disorders") (6,28). The main reason these youth are diagnosed with BP-NOS is because the manic symptoms are not present for sufficient time to meet the DSM duration criteria for a manic, hypomanic, or mixed episode; and/or they do not have enough symptoms. One large study comparing the presentation of youth with an operationalized diagnosis of BP-NOS with those who met full criteria for BP-I found that BP-NOS subjects differed from those with BP-I primarily on duration and severity of manic symptomatology, but not on the fundamental phenomenology of manic symptoms, comorbid disorders, or family psychiatric history (6,23). The majority of BP-NOS youth fulfilled the mood and symptom criteria for mania and/or hypomania, but did not meet the 4-day duration criteria for a hypomanic episode or the 7-day duration criteria for a manic/mixed episode. BP-NOS youth are younger, have more chronic course, irritability, mixed presentations with less euphoric mania than BP-I, but otherwise phenomenologically in continuum with BP-I (23,28,29). Moreover, BP-NOS youth have as much impairment, risk for suicidality and

substance abuse, presence of comorbid disorders and family history of mania as youth with BP-I, and about 50% progress to meet the DSM-IV criteria for BP-I or BP-II disorders (28–32).

Youth can also be diagnosed with cyclothymic disorder, a condition manifested by at least 1 year of several episodes with hypomanic symptoms and episodes with depressive symptoms that do not fulfill the criteria for a hypomanic episode or an MDE (33). Youth with these symptoms are difficult to differentiate from BP-NOS.

Attributing Symptoms to Bipolar Disorder Versus Other Psychiatric Disorders

As described later in more detail under Differential Diagnosis, clinicians must be cautious about attributing symptoms to mania or hypomania unless they show a clear temporal association with the abnormally elevated, expansive, and/or irritable mood. The manic syndrome exists as a collection of concurrent symptoms and mood abnormalities, not a list of symptoms that occur in temporal isolation. Chronic symptoms such as hyperactivity or distractibility generally should not be considered evidence of mania unless they clearly intensify with the onset of abnormal mood. Prolonged presentations of nonspecific manic-like symptoms that do not change in overall intensity and appear episodically should raise the possibility of an alternative psychiatric diagnosis.

EPIDEMIOLOGY

Retrospective studies in adults with BP have consistently reported that up to 60% experienced onset of their mood symptoms before age 20 (25,26). However, due to the difficulties and controversies regarding the diagnosis of pediatric BP, it is not clear what the real prevalence of this disorder is in youth.

Over the last several years, the “administrative” prevalence (the number of children diagnosed with “BP” in clinical settings) of BP in youth has significantly increased, particularly in the United States (34). This increase may be accounted for by factors such as increased awareness, referral biases, and misdiagnosing youth with BP. However, due to the fact that pediatric BP was rarely diagnosed in the past, any small increment in the rate of diagnosis will produce a large increment of the administrative prevalence of this condition. In contrast to the above results, a recent meta-analysis showed that the “true prevalence” of pediatric BP-I and II does not differ among countries, with rates of 1% to 2% that increase during late adolescence (35,36). Dissimilarly, the prevalence of BP-NOS or “soft” subsyndromal symptoms varies among studies, with a prevalence as high as 6% in the United States (36).

COMORBIDITY

COMORBIDITY

Pediatric BP is usually accompanied by other psychiatric disorders. A recent meta-analysis reported that the average weighted rates were as follows: ADHD 53%, ODD 42%, conduct disorder 27%, and anxiety disorders 23% (7). As expected, given the relatively young mean age of the sample, substance abuse was present in 9%. However, substance use disorders (SUD) progressively increases with age (32,37). To a lesser degree, other psychiatric disorders, such as obsessive–compulsive disorder as well as medical conditions, can accompany BP. However, the results are heterogeneous and depend on factors such as the setting where the data were collected, instruments used, clinical experience of the interviewer, and methods to interpret the data. In any case, the presence of these disorders affects the youth's response to treatment and prognosis, indicating the need to identify and treat them effectively.

DIFFERENTIAL DIAGNOSIS

As noted above, it is difficult to diagnose pediatric BP because of variability in the clinical presentation (severity, subtype of BP disorder, phase of the illness), high comorbidity and overlap in symptom presentation with other psychiatric disorders, effects of development on symptom expression, children's difficulties describing their symptoms, the environmental context in which the BP is developing (e.g., high family conflict, abuse), and potential effects of any psychotropic medications prescribed (9,38,39).

The main psychiatric conditions that can be challenging to differentiate from pediatric BP are ADHD, disruptive behavior disorders (ODD and conduct disorder), DMDD (and its predecessor severe mood dysregulation [SMD]), unipolar depression, ASD, schizophrenia and other psychotic disorders, substance abuse disorders, and in adolescents, borderline personality disorder. Medical and neurologic illnesses (head trauma, brain tumors, hyperthyroidism), and side effects of medications (corticosteroids, antidepressants, and stimulants) may also be accompanied by mood fluctuations that may mimic BP. Additionally, normal mood variability sometimes may be misinterpreted as symptoms of hypomania. In daily practice, severe disruptive behavior disorders and ADHD are the most frequent conditions that may be confused with BP (Tables 5.4.2.4 and 5.4.2.5). There are some symptoms that mainly occur in BP youth and may help to differentiate between BP and these disorders, such as clinically relevant euphoria, grandiosity, decreased need for sleep, hypersexuality (without history of sexual abuse or exposure to sex), and hallucinations (6,10,11,38,39). Some of the symptoms shared between BP, ADHD, and behaviorally disordered children, such as increased energy, irritability, and aggression, can be much more severe in BP youth. The course of the symptoms

over time, the presence of family history of BP, and other issues described in Tables 5.4.2.4 and 5.4.2.5 also may help distinguish between BP and these disorders.

Most depressed youth seen at psychiatric clinics are experiencing their first episode of depression (23,39). Some of these youth may develop BP, but so far it is almost impossible to know at the time of first assessment who will go on to develop BP. Thus, a careful assessment for history of syndromal and subsyndromal manic or hypomanic symptoms is indicated. Also, the presence of psychosis, family history of BP, and pharmacologically induced mania/hypomania may indicate susceptibility to develop BP (40–44).

TABLE 5.4.2.4

BIPOLAR DISORDER VERSUS ATTENTION DEFICIT HYPERACTIVE DISORDER (ADHD)[a]

Suspect the presence of bipolar disorder in a child with ADHD if:

- The ADHD symptoms appeared later in life (e.g., at age 10 yrs old or older).
- The symptoms of ADHD appeared abruptly in an otherwise healthy child.
- The ADHD symptoms were responding to stimulants and now are not.
- The ADHD symptoms come and go and tend to occur with mood changes.
- A child with ADHD begins to have periods of exaggerated elation, grandiosity, depression, no need for sleep, inappropriate sexual behaviors.
- A child with ADHD has recurrent severe mood swings, temper outbursts, or rages.
- A child with ADHD has hallucinations and/or delusions.
- A child with ADHD has a strong family history of bipolar disorder in his or her family, particularly if the child is not responding to appropriate ADHD treatments.

[a]A child may have both ADHD and BP. Moreover, the noted clinical situations may also be due to other psychiatric disorders (unipolar depression, substance abuse), medical problems (thyroid problems, seizures, tumors), use of medications (prednisone), and environmental stressors (family conflict, chaotic environment, sexual or physical abuse) that may coexist with ADHD.

TABLE 5.4.2.5

BIPOLAR DISORDER VERSUS DISRUPTIVE BEHAVIOR DISORDER

- If the behavior problems *only* occur while the child is in the midst of an episode of mania or depression, and the behavior problems disappear when the mood symptoms improve, the diagnoses of oppositional or conduct disorder should not be made.
- If a child has “off and on” oppositional or conduct symptoms or these symptoms only appear when the child has mood problems, the diagnosis of BP (or other disorders such as recurrent unipolar depression or substance abuse) should be considered.
- If the child had oppositional behaviors before the onset of the mood disorders, both diagnoses may be given.
- If a child has severe behavior problems that are not responding to treatment, consider the possibility of a mood disorder (bipolar and nonbipolar depressions), other psychiatric disorder (ADHD, substance abuse), and/or exposure to stressors.
- If a child has behavior problems and a family history of BP disorder, consider the possibility that the child has a mood disorder (unipolar major depression or BP disorder).
- If a child has behavior problems and is having hallucinations and delusions consider the possibility of BP disorder. Also consider the possibility of schizophrenia, use of illicit drugs/alcohol, or medical/neurologic conditions.

Reprinted from Birmaher B: *New Hope for Children and Adolescents with BP Disorders*. New York,

Three Rivers Press, a division of Random House, Inc., 2004, with permission.

DMDD (and SMD) is characterized by impairing, chronic irritability that can be misdiagnosed as BP, but this disorder does not have distinct manic episodes (45). Moreover, perhaps with the exception of severely irritable youth with positive family history of mania, longitudinal data indicate that youth with SMD are not at high risk to develop BD as they age (45).

Schizophrenia is rare in children and sometimes BP may manifest with psychosis and bizarre behaviors. Therefore, mood disorders need to be ruled out in any child with psychosis. Substance abuse may also induce severe mood changes that may be difficult to differentiate from BP. In these cases, if the symptoms of mania continue after the youth is no longer using substances, there is an increased likelihood of a BP diagnosis. Moreover, youth with mood disorders are at higher risk for using illicit drugs or alcohol as a way to deal with their mood and stressors (32,38). Finally, although there is controversy about the validity of borderline personality disorder in youth, some BP teens, particularly those with BP-II, may be misdiagnosed as having this condition (and vice-versa).

The use of medications such as antidepressants may unmask or trigger a manic or hypomanic episode in a susceptible individual (46). However, not every child who becomes agitated or giddy and excited with these or other medications has BP. Family history, the severity, length, and quality of manic symptomatology may help to differentiate between BP and agitation induced by these or other medications (47).

COURSE AND OUTCOME

Although there are methodologic differences among the current pediatric prospective naturalistic studies, they have consistently shown that 70% to 100% of children and adolescents with BP will eventually recover (i.e., no significant symptoms for at least 2 months) from their index episode (23,39,48,49). However, of those who recover, up to 80% will experience one or more recurrences in a period of 2 to 5 years. BP youth have high rates of hospitalizations and health service utilization, and they are at risk for psychosis, suicidality, substance abuse, unemployment, legal problems, abuse, and poor academic and psychosocial functioning (22,23,30–32). The ongoing BP symptoms may also have a negative impact on the family, marital, and sibling relationships, as well as on family finances. The considerable impairment in psychosocial functioning reported in these studies is not only due to the fact that most of them were carried out in clinical samples, but also similar findings have been reported in BP adolescents never referred for treatment (50,51).

Recent studies show that BP is not only manifested by punctuated recovery and recurrences, but by ongoing fluctuating syndromal and subsyndromal symptomatology (23). In fact, in a recent 4-year follow-up study, for approximately 60% of the

observation time, BP youth experienced syndromal and subsyndromal BP symptoms, particularly depressive and mixed symptoms (Fig. 5.4.2.1) (23). In addition, pediatric BP frequently manifests with repeated changes in symptom polarity (22–24,39). These rapid fluctuations in mood appear to be more accentuated than in adults with BP and may explain, at least in part, the difficulties encountered in diagnosing and treating BP symptoms in youth (Fig. 5.4.2.2) (23,29,52). Youth diagnosed with BP-NOS are at high risk to convert to BP-I/II, with rates of conversion as high as 45% (28). To date, the main risk factor found to be associated with conversion into BP-I is family history of mania.

The above noted studies evaluated the course and outcome of BP as a group. A recent study evaluated more individualized course during a 9-year period using latent growth class analyses (48). Four longitudinal mood trajectories were found: (1) “predominantly euthymic” course (24.0%); (2) “moderately euthymic” course (34.6%), “ill with improving course” (19.1%), and “predominantly ill” course (22.3%). Within each group, youths were euthymic on average 84.4%, 47.3%, 42.8%, and 11.5% of the follow-up time, respectively. The fact that a substantial group of youth have good course gives youth and their families hope that BP disorder does not necessarily convey poor prognosis. Nonetheless, continued syndromal and subsyndromal mood symptoms in all four classes underscore the need to optimize treatment.
FIGURE 5.4.2.2. Change in polarity: Switch between depression and mania/hypomania or vice versa with or without intervening weeks at the asymptomatic status. Comparison between youth with BP-I versus adults with BP-I. All comparisons are significant at $p < 0.001$. (Data from Birmaher B, Axelson D, Strober M, et al.: Clinical course of children and adolescents with bipolar spectrum disorders. *Arch Gen Psychiatry* 63:175–183, 2006; and Judd LL, Akiskal HS,

Schettler PJ, et al.: The long-term natural history of the weekly symptomatic status of bipolar I disorder. *Arch Gen Psychiatry* 59:530–537, 2002.)

Overall, across the extant studies the following factors have been associated with worse course and outcome: early age of onset, long duration, mixed or rapid cycling episodes, psychosis, presence of subsyndromal mood symptoms, comorbid disorders, exposure to negative life events (e.g., abuse), and family psychopathology (mood disorders and substance abuse) and low socioeconomic status (22,23,48,49).

RISK FACTORS

Twin, Adoption, and Family Studies

Twin and adoption studies have demonstrated that BP runs in families (39,53–56). The prevalence of BP in first-degree relatives of adults with BP is increased 8- to 10-fold over the expected prevalence of BP in community samples of adults, making BP one of the most familial psychiatric disorders (39,54,57–60). However, the rates of BP in relatives of BP subjects may be underestimated because most BP high-risk studies included only offspring of BP parents older than 18 years (54) without considering that many adults with BP experienced their first symptoms of BP early in life (3,25,26,39,61).

A large prospective high-risk BP study (mean follow-up 7 years), the Pittsburgh Bipolar Offspring Study (BIOS), that included offspring of parents with BP and control offspring of healthy parents and parents with non-BP psychiatric disorders (with raters blind to parental diagnosis) showed that after adjusting for confounding factors, in comparison with offspring of community controls, offspring of BP parents had significantly higher rates of BP spectrum disorders (23% vs. 3%, respectively) (57,58,61), high rates of BP-I (13% and 1.5%, respectively), and anxiety disorders. The presence of subthreshold manic or hypomanic episodes, MDEs, and disruptive behavior disorders was associated with subsequent manic, mixed, or hypomanic episodes. However, only subthreshold manic or hypomanic episodes were associated when analyses were restricted to prospective data.

The above study analyzed categorical disorders. A more recent analyses of the dimensional symptoms preceding the onset of BP showed that offspring with mood lability, depression/anxiety, and particularly those with subsyndromal manic symptoms and whose parents had early-onset BP were at 50% risk to develop BP (61).

In addition to the above high-risk family investigations, “bottom-up” studies also provide further evidence of the familial nature of BP (39,59). These studies have shown increased risk for BP and depression in first-degree relatives of youth with

BP when compared with relatives of adolescents with other disorders. Further, the first-degree relatives of youth whose BP started early in life, adolescents with subsyndromal symptoms of BP, and BP children with comorbid ADHD, showed a significantly increased risk for mood disorders when compared with youth without these factors.

Genetic Studies

Extant literature has demonstrated a genetic etiology for BP with an estimated heritability at over 80% (53,54,56,62,63). Current literature suggests that multiple (interacting) loci and epigenetic factors may contribute to BP liability, but the effect of each gene is small (63,64). Moreover, variation in ascertainment, phenotype definition, control selection, limited power, and possible confounding by population substructure has led to inconsistent results.

Spectroscopy Studies

The most common spectroscopic imaging method used in BP research is ^{1}H-MR spectroscopy. Glutamatergic ^{1}H-MR spectroscopy metabolites include Glu, Gln, γ-aminobutyric acid (GABA) and *N*-acetyl aspartylglutamate (65). These compounds seem to be affected in the frontostriatal region, cingulate cortex, dorsolateral prefrontal cortex (DLPFC), and other areas of the brain in BP youth and offspring of BP parents (66–70). A recent review concluded that the predictive value of MR spectroscopy neuroimaging may relate to a disturbance in either glutamine or GABA, or in the homeostatic equilibrium of Glu and glutamine, providing further support for the exploration of the Gln/Glu ratio as a potential biomarker in pediatric BP (71). BP youth in a manic or mixed episode were treated with valproic acid and performed ^{1}H-MR spectroscopy at baseline, day 7, and day 28 (70). In subjects who achieved clinical remission with valproic acid, the investigators found a decreased baseline glutamate and a correlation between a change in the Young Mania Rating Scale (YMRS) scores and decreased Glu in the left ventrolateral prefrontal cortex. Furthermore, overall, mitochondrial studies of MR spectroscopy revealed reduced intracellular pH and that adenosine diphosphate is one of the principal controllers of oxidative metabolism (71).

Neuroimaging Studies

A recent meta-analyses showed that in contrast to BP adults, emotional dysfunction is associated with hyperactivation of the amygdala, prefrontal, and visual system and cognitive deficits with hypoactivation of the anterior cingulate cortex (72–75). Studies in BP youth also demonstrate abnormally decreased amygdala volumes,

decreased OFC and anterior cingulate cortex (ACC) gray matter; abnormally reduced fractional anisotropy (FA) in white matter tracts connecting prefrontal and subcortical region; and altered resting state in prefrontal cortical circuitry and large scale networks (73–80).

Neuroimaging findings in BP youth thus may be conceptualized as parallel dysfunction in bilateral prefrontal cortical (especially vlPFC)–hippocampal–amygdala emotion processing and emotion regulation neural circuitries, together with an "overactive" left-sided ventral striatal–vlPFC–OFC reward processing circuitry, that results in characteristic behavioral abnormalities associated with BP: emotional dysregulation, heightened reward sensitivity, and predisposition to mania (73). A potential structural basis for these functional abnormalities is decrease in white matter tracts connecting prefrontal and subcortical regions that may suggest abnormal myelination or abnormal orientation of axons in these tracts, and gray matter decreases in prefrontal and temporal cortices, amygdala, and hippocampus. Resting state connectivity studies are beginning to provide evidence in support of intrinsic functional abnormalities in these neural circuitries in adults with BD.

A limitation of the current literature is the inadequate information of the impact of previous clinical mood and nonmood symptoms course and treatment upon neural functioning and structure. Prospective longitudinal follow-up studies are also critically needed to elucidate the extent to which measures of neural functioning and structure predict future course. Regarding the effects of treatment, imaging findings in BP have preliminarily reported that prefrontal cortical regions improve in function with some pharmacologic agents, while amygdala in the subcortical region does not reach normality until after longer-term treatment (15,81). Also, various medications differentially engage different brain circuitry regions, suggesting the possibility that combined therapy may be required based on severity and/or presentation.

Regarding the effects of nonmood symptomatology, preliminary evidence from studies that contrasted BD and ADHD suggests that the neural systems involved in impulsivity, reward systems, and executive function were engaged differently in the two illnesses. In BP, "emotional impulsivity" is predominantly emotionally driven, and stems from ventral frontostriatal-limbic circuitry dysfunction. In contrast, in ADHD "cognitive impulsivity" is predominantly cognitively driven, and stems from dorsal frontostriatal dysfunction (82).

Neurocognitive Function

The neurocognitive studies have limitations similar to those described under neuroimaging studies above. Extant literature has found that in comparison with healthy controls and youth with other disorders, BP youth show cognitive impairment in attention, set-shifting, working memory, and in particular, cognitive flexibility (adaptation in response to changing rewards and punishments) (83–85). These

findings have also been observed in BP youth during periods of euthymia (86). Similar results have been reported in BP adults (87). There is also widespread agreement that cognitive functioning independently and robustly predicts later functional outcomes in BP (88). However, the trajectory of cognitive functioning into adulthood in young BP patients remains largely unknown. Some data support a neuroprogressive model of worsening cognitive function over the course of illness (86–90), while other reports dispute this (91–93). The neurocognitive studies have limitations similar to those described under neuroimaging studies above. However, some studies, but not all (75,81) suggest that impairment in cognitive functioning (e.g., flexibility) in BP youth may be independent of mood state and treatment exposure (83–85).

Psychosocial Factors

Very few studies have evaluated the effects of psychosocial factors on the onset and maintenance of BP in youth. These studies have suggested that low socioeconomic status (SES), exposure to negative events (e.g., abuse), and stressful family environments (i.e., high "expressed emotion" [EE]) are associated with poor prognosis (22,23,39,93). In BP adults, high EE, negative events, poor sleep hygiene, and irregular daily routines have been associated with increased risk for recurrences (64,95).

ASSESSMENT

This section briefly describes instruments and rating scales used to assess BP symptoms in youth. For further information regarding these scales and for the description of instruments related to the assessment of depressive, suicidal, and other psychiatric conditions, see Chapter 4.3 and the parameters for the psychiatric assessment of children and adolescents (96).

Psychiatric Interviews

There are several structured and semistructured interviews that can be used for the diagnosis of BP and for the evaluation of subtype and the frequency, intensity, number, and duration of each episode. The most widely used interviews in BP studies are two similar instruments: the Kiddie Schedule for Affective Disorders and Schizophrenia for School Age Children—Present and Lifetime version (K-SADSPL) (97) and the Washington University KSADS (WASH-U-KSADS) (98). However, these interviews are lengthy, and thus mainly used for research purposes. Symptom checklists based on the DSM criteria for BP as well as depressive disorders are also useful in clinical settings.

Clinician-Based Rating Scales

Two clinician-based rating scales are currently used for the assessment of manic symptoms in youth, the YMRS (99) and the KSADS Mania Rating Scale that was derived from the KSADS-P mania module (KSADS-MRS) (100). However, a recent study found that the YMRS is not a valid instrument for BP disorder in youth (101).

Youth, Parent, and Teacher Rating Scales

The above noted meta-analysis reported that in general, existing scales help to screen youth with BP from youth with other disorders (101). However, scales that include manic symptoms outperformed those with general symptom checklists. Among the scales that include manic symptoms, the General Behavior Inventory (GBI) (102), the Child Mania Rating Scale (CMRS) (103), and the Mood Disorders Questionnaire (104) have been validated in many studies and appear to be the most helpful in clinical practice. Caregiver reports are more effective in identifying mania than youth or teacher reports. Nevertheless, multiple informants and directly interviewing the youth increase the validity of the diagnosis.

Of note, studies using a scale that includes general symptoms of psychopathology, the Child Behavior Checklist (CBCL), found a consistent pattern of elevated scores on subscales assessing aggressive behavior, attention problems, delinquent behavior, and anxious/depressed domains in BP youth (105–107). However, more recent studies have demonstrated that the above symptoms are a proxy for severe psychopathology and not specific for BP (101,108).

Mood Timelines or Diaries

Mood timelines or diaries using school years, birthdays, and holidays as anchors are very helpful in the assessment of the onset and course of mood disorders. These instruments use colors or numeric ratings (e.g., from 0 to 10) to chart daily changes in mood along with any corresponding stressors, illnesses, and treatments. These instruments can help children, parents, and clinicians to visualize the course of their mood, and identify events that may have triggered the depression, hypomania/mania, or irritability and examine the relationship between treatment and response. Several electronic mood charts (e.g., websites, mobile applications) exist to evaluate daily mood fluctuations, but they vary widely in quality and usefulness.

Other Assessments

Clinicians should always evaluate for psychosocial functioning, family

psychopathology, ongoing negative life events (family conflicts, abuse), functioning in several areas (peer relationships, school functioning, work), and for the presence of psychiatric and medical conditions and suicidal and homicidal ideation (for instruments to evaluate these domains, see the respective chapters). If the youth has learning difficulties before the onset of the mood disorders or these difficulties continue when the mood is stable, neuropsychologic testing is warranted (Chapter 4.4). Also, the clinician together with the child and parents should evaluate the appropriate intensity and restrictiveness of care (hospitalization). The decision for the level of care will depend on factors such as the severity of mood symptoms, presence of suicidal and/or homicidal symptoms, psychosis, substance dependence, agitation, child's and parents' adherence to treatment, parental psychopathology, and family environment.

At the present time, no biologic or imaging tests are clinically available for the diagnosis of BP.

TREATMENT

Phases of Treatment

The treatment of BP is usually divided into acute, continuation, and maintenance phases. The main goal of the acute treatment phase is to control or ameliorate the acute BP symptoms that are affecting the child's psychosocial functioning and well-being or endangering the child's life. Continuation treatment is required to consolidate the response during the acute phase and avoid relapses, and maintenance treatment is designed to avoid recurrences. Pharmacologic and psychosocial treatment strategies for each one of these three treatment phases are discussed below. In general, the choice of treatment depends on the severity, phase of illness, subtype of BP, chronicity, comorbid disorders, subject's age, family and patient preference and expectations, availability of services, family and environmental circumstances, and family psychopathology.

During each of the three treatment phases noted above, if a child does not respond to treatment, factors associated with nonresponse need to be considered, such as misdiagnosis, poor adherence to treatment, presence of comorbid psychiatric and medical conditions, and ongoing exposure to negative events (family conflict, abuse).

Support, Psychoeducation, and Case Management

At any phase of treatment, basic elements of support are indicated, including active listening. Provision of hope is critical, particularly in the face of demoralization that may occur for the youth and his/her parents both in the early phases of diagnosis and treatment, and during periods of relapse.

Psychoeducation is a common component of most manualized psychosocial treatments for pediatric BP, and data suggest its provision is associated with improved treatment adherence and reduced mood symptoms (109–111). It is important to provide psychoeducation to both the patient and family members about the causes, symptoms, course, and different treatments of BP and the possible risks and benefits associated with these treatments (and with no treatment at all). Attention should be given to helping the youth and family understand the genetic, biologic, and psychosocial influences associated with onset of mood disorders. Additionally, providers should prepare the youth and family for what may be a recurrent and chronic illness with frequent fluctuations in mood and functioning. Often, it is hard for parents and youth to accept the illness, and therefore, to adhere to treatment. A discussion highlighting the import of adherence to both medication and psychosocial treatment is therefore critical, and optimally includes identification and problem-solving potential barriers to adherence in any individual case (e.g., irregular schedules, side effects, etc.). Furthermore, psychosocial treatment should involve helping youth and parents recognize symptoms of both depression and hypomania/mania, and distinguish symptoms associated with BP (e.g., negative thinking and mood swings) from normal developmental processes (e.g., individuation in adolescence) and also from symptoms of other psychiatric disorders (e.g., oppositionality in behavioral disorders, impulsivity in ADHD). Sleep hygiene and routine are important, especially in view of sleep deprivation leading to worsening of symptoms. Ensuring a stable circadian rhythm has a positive effect on physiology and daily functioning. To further assist with psychoeducation in clinical practice, websites and books are available (112,113).

Case management is frequently an important component of treatment for BP youth and their families. This often involves coordination and ongoing contact with school personnel, who may need education to help understand the disease model of BP. Alongside parents, providers must help advocate for adequate accommodations (e.g., schedule, workload) to help the child succeed academically. Additionally, providers may need to help negotiate with parents and/or other organizations regarding reasonable expectations for the child based on his/her current symptoms, with the recognition that needs will likely change over time (113–115).

Acute Treatment

In this chapter, the term mood stabilizer refers to lithium and anticonvulsants such as valproate, carbamazepine, and lamotrigine. However, the extant literature seems to indicate that the atypical antipsychotics may also operate as mood stabilizers.

In general, and until further studies are available, doses of mood stabilizers and atypical antipsychotics and blood levels of mood stabilizers are similar to those used in BP adults (116–119). It appears that the pharmacokinetics of these medications is

similar across age (120). However, a small study that deserves replication showed that youth demonstrate lower brain-to-serum lithium concentration ratios than adults, suggesting that youth may need higher serum lithium concentrations (121).

In any case, to avoid unnecessarily high dosages and decrease the risk of side effects and poor adherence to treatment, unless the youth is too agitated, it is recommended to start at low dosages and increase slowly according to response and side effects.

PHARMACOTHERAPY

Mania/Mixed Episodes

Current studies suggest that the most efficacious and fastest way to yield response for acute manic/mixed episodes is with the atypical antipsychotics (122–125). The mood stabilizers are less efficacious, but most studies only lasted 8 weeks—possibly insufficient time to observe the true response to these medications (125–129). Also, there is variability in response to mood stabilizers depending on the site of the study and the sample size. A recent multicenter study, the Treatment of Early-Age Mania (TEAM), randomly administered risperidone (average dose 3 mg), lithium (average blood levels 1.1), or valproate (average blood levels 114) to 279 youth (ages 6 to 15 years old) with BP-I (130). The treatment was open, but the assessments were blind to treatment assignment. After 8 weeks of treatment, roughly 70% of the youth responded to risperidone, 30% to lithium, and 20% to valproate. The response to risperidone was similar across sites, but in some sites, the response to lithium was higher (128). An analysis of the benefits of either an add-on or a switch of antimanic medications for an 8-week period in partial and nonresponders, respectively, showed better response to risperidone than lithium or valproate (131). A small 6-week study comparing valproate versus risperidone versus placebo for preschool BP also showed that risperidone was efficacious, but not valproate (129). These studies have also suggested that the combination of two mood stabilizers such as lithium and valproate or a mood stabilizer with an atypical antipsychotic appears to be superior to mood stabilizer monotherapy, with responses ranging from 60% to 90% (132–136). Open treatment with carbamazepine indicates that this medication appears to be effective and safe for BP youth, but randomized control trials (RCTs) are needed to confirm this (137). A RTC for oxycarbamazepine was negative (138).

Although there are no studies, for youth who require prompt response (e.g., agitation, psychosis), it is possible to start treatment with a mood stabilizer and antipsychotic, and once the youth is stable consider tapering the antipsychotic. However, atypical antipsychotic monotherapy may serve as an alternative choice. For adolescents with severe illnesses that are resistant to these treatments, electroconvulsive therapy (ECT) should be considered (139).

Hypomania, BP-NOS, and Cyclothymia

Despite the increased morbidity associated with these disorders, there are very few open studies that specifically address the treatment of youth with these conditions. Therefore, until research is available, for those youth with significant impairment, similar psychosocial and pharmacologic treatments to those described for mania are recommended.

Depression

BP youth spend substantial amounts of time with syndromal or subsyndromal depressive symptoms that significantly impair their psychosocial functioning and increase their risk for suicide (9,23,30). However, the very few studies for depressed BP youth are pharmacologic RCTs with small samples and open-label studies.

In adults, monotherapy with lithium, valproate, some of the atypical antipsychotics, and the combination of these medications are indicated for the acute treatment of depression (117,140). Although controversial, the judicial use of the serotonin reuptake inhibitors (SSRIs) or bupropion in combination with mood stabilizers, and/or the typical antipsychotic, may also be beneficial for some youth with BP depression (117,140). SSRIs or other antidepressants may trigger mania, hypomania, mixed episodes or rapid cycling, or agitation, particularly when used without concomitant mood stabilizer treatment. A recent 8-week RCT comparing quetiapine versus placebo for a small sample of BP-depressed youth was negative (141). Finally, a secondary analysis of the TEAM study showed that depressive symptoms, present in the acutely manic/mixed phase of BP, equally improved with risperidone, lithium, and valproate (142). However, risperidone yielded more rapid improvement than the other two medications.

Until more studies become available, and taking into account the limitations of extrapolating from the adult literature, it is recommended to use lithium, valproate, or the atypical antipsychotics as first-line medications for BP depression. For partial or nonresponders, combinations of these medications with atypical antipsychotics, SSRIs, or bupropion are indicated.

As described below, specific psychosocial treatments designed for BP youth appear to be efficacious for the treatment of BP symptoms, particularly depression. These treatments should also be considered as the first line of treatment, especially for youth with mild-to-moderate depression. For subjects with recurrent seasonal depression, light therapy should be considered (143). For adolescents with severe and treatment-resistant disorders, electroconvulsive treatment (ECT) may be indicated (139). Other treatments such as transcranial magnetic therapy (TMS) or augmentation with omega-3 fatty acids (144,145) appear promising, but they need to

be further evaluated.

Rapid Cycling

There are no specific studies for the treatment of rapid cycling in youth. Until these studies become available, the same treatments as for mania or mixed episodes are recommended (116).

Adjunctive Medications

Almost all studies use short-term adjuvant medications or rescue paradigms during the acute phase of treatment with monotherapy or combination regimes. This strategy, in fact, becomes inevitable in managing breakthrough symptoms of mania in BP disorder. Lorazepam and clonazepam or short administration of antipsychotics sometimes may be temporarily used for the management of acute agitation or insomnia (39,116).

Psychosocial Treatments

In addition to supportive psychotherapy, specific psychosocial treatment packages for youth with BP are at various stages of investigation that target acute affective symptoms and prevention or delay of recurrences, improvement of adherence to treatment, and management of comorbid conditions. A central feature of all psychosocial treatment models for pediatric BP includes psychoeducation, problem-solving, and coping skills. Parents are closely engaged in their children's therapy and referred to treatment if they have clinically significant symptoms themselves.

To date, five distinct psychosocial approaches have been developed and are at various stages of evaluation, each with a specified target age group and method of delivery (e.g., group vs. individual treatment). First, child- and family-focused cognitive behavior therapy (CFF-CBT) was specifically designed for 8 to 12 year olds with BP (146). This approach integrates core principles of CBT with those of family-focused therapy (FFT; see below) in a 12-session intervention designed to be largely delivered jointly with parents and children. Data from open studies and an RCT suggest CFF-CBT is associated with improvement in functioning, mood symptoms, and treatment adherence (146,147). Second, Fristad et al. (110,111) employed an 8-session multiple-family group treatment for youths aged 8 to 12 years with bipolar and depressive spectrum disorders. This approach includes an emphasis on psychoeducation around the role of medications, and coping skills including problem-solving and communication skills. Studies show that multi-family psycho-education group therapy (MFPG) (vs. control condition) is associated with greater mood improvement, enhanced family interactions, subsequent treatment engagement,

and greater knowledge around mood disorder (110,111,114). Third, Miklowitz et al. (2004) (115), developed a 9-month (21 session) manualized version of FFT specifically for adolescents with BP and their parents that includes psychoeducation geared toward illness management, skills to solve problems, and building communication skills to decrease stress and conflict in the family environment. A preliminary study using FFT for BP adolescents showed symptomatic improvement in mania, depression, and behavior problems at the end of 1 year of follow-up (115). A subsequent randomized trial showed less severe depressive symptoms and faster recovery from depression among adolescents receiving FFT as compared with a brief educational intervention (148). However, a more recent randomized trial failed to replicate these findings (148,149). Next, Goldstein et al. (2007) (149) developed a 1-year adaptation of Dialectical Behavior Therapy (DBT) (151) for adolescents (age 12 to 18) with BP and their family members. This approach includes both individual and family skills training sessions to provide psychoeducation, and also teach and ensure generalization of skills targeting mindfulness, emotion dysregulation, distress tolerance, interpersonal effectiveness, and parent–child conflict (150). A recent randomized trial showed adolescents receiving DBT (as compared with psychosocial treatment as usual) demonstrated less severe depressive symptoms and greater likelihood of improvement in suicidal ideation (151). Finally, Hlastala and Frank (2006) (152) adapted Interpersonal and Social Rhythm Therapy for BP adolescents ages 12 to 18 years old. This intervention highlights the connection between difficulties in relationships and mood, alongside regularizing sleep and daily rhythms as a means of preventing and improving mood symptoms in BP. This 16-session adaptation is primarily conducted with the adolescent, but family involvement is recommended. In one open study, Hlastala et al. (2010) (153) showed improvement from pre- to posttreatment in mood symptoms with interpersonal and social rhythm therapy (IPSRT). With respect to psychosocial treatment of common comorbid conditions (e.g., oppositional behaviors, substance abuse, anxiety disorder), efficacious psychosocial treatments are indicated (see respective chapters). In sum, additional research is needed to establish efficacy and determine fit between the psychosocial approaches and the individual patient most likely to respond. Nonetheless, these developmental adaptations, with significant consensus on core shared principles (e.g., psychoeducation, problem-solving, skill building), offer promise as adjunctive treatment.

Recent studies have also begun to explore the potential for early psychosocial intervention to ameliorate, delay, or even prevent the onset and/or progression of BP among youth at high risk for the disorder. Goldstein et al. (2013) (154) developed a modification of IPSRT for the adolescent offspring of parents with BP who themselves have not yet developed BP. An open pilot study demonstrated the feasibility and acceptability of the intervention for this group, and identified pre- to posttreatment improvement in sleep and circadian patterns that may contribute to

increased risk for illness onset. Results from a recently completed RCT will further inform the field regarding efficacy. Additionally, given the risk for youth with mood disturbance and a positive BP family history to develop BP and progress to BP-I/II over time, Miklowitz et al. (155,156) examined whether FFT-A could be a beneficial early intervention for mood-disordered adolescents (i.e., those with BP-NOS, cyclothymia, depression) with a family history of BP. An initial pilot study demonstrated feasibility and improvement pre- to posttreatment in depression, hypomania, and functioning (155). A subsequent RCT showed more rapid recovery from mood symptoms, more weeks symptom free, and lesser manic symptoms over 1 year among high-risk youth receiving FFT-A as compared with those receiving a single-session family educational intervention; effects were more pronounced among high EE families (116). Clearly, further study of the role of early intervention for at-risk youth is warranted to determine timing and selection of those most likely to benefit.

CONTINUATION AND MAINTENANCE TREATMENTS

Randomized controlled trials in adults have suggested the use of valproate, lithium, lamotrigine (only for depression), and atypical antipsychotics for prevention of new mood episodes in stable BP adults (118). In any case, the first-line maintenance treatment is the same regimen that successfully treated the manic episode (118). The literature examining ongoing treatment for BP youth is limited and most studies have been open. An 18-month naturalistic follow-up study of BP adolescents who were stable on lithium therapy found a relapse rate of 92% in adolescents who stopped lithium treatment, compared to 38% to those who continued with lithium (157). Two controlled studies have been published examining how BP youth who remitted from acute manic symptoms while taking combination treatment responded to a switch to monotherapy. In the first, 6 out of 14 BP adolescents who were stabilized from an acute psychotic manic episode after 4 weeks of treatment with lithium and an antipsychotic relapsed within 1 week of discontinuation of the antipsychotic (135). In the second, subjects stabilized on lithium and valproate combination therapy were switched to either drug alone (134). There was no difference between the two drugs, and the majority of subjects had relapsed within 4 months of switching to monotherapy. An extended follow-up phase of this study found that approximately 90% of the subjects who had a mood relapse responded to restarting the combination treatment (158). A recent RCT showed that aripiprazole 10 mg/day or 30 mg/day were superior to placebo and generally well tolerated in BP-I youth up to 30 weeks. However, completion rates were very low in all treatment arms (122,159).

The duration of the maintenance treatment depends on many factors such as the duration of the illness, lifetime number of episodes, severity and history of hospitalizations, psychosis, and suicidality. In general, BP youth with clear BP may

require many years of treatment and some lifelong. However, some BP youth, particularly those with late onset, less severe mood episodes, less comorbid disorders, high SES, less history of sexual abuse, and less family history of mood and substance use disorders may have long mostly euthymic course (23,48), careful medication taper may be considered once remission has been maintained for 12 to 24 months. Also, it may be reasonable to consider shorter treatment in cases when the diagnosis is not clearly established or the illness has been relatively mild. Conversely, severe and recurrent illness may merit more prolonged maintenance pharmacotherapy. The optimal duration of psychosocial treatments for pediatric BP has not been established. Given that BP may be best viewed as a chronic disease, it is reasonable to provide some level of ongoing psychosocial support, crisis management, and formal therapy booster sessions when appropriate.

ACUTE AND LONG-TERM PHARMACOTHERAPY SIDE EFFECTS

For a comprehensive review refer to Chapter 6.1.1. In this section we highlight practical aspects of the pharmacologic management of BP.

Lithium

The most serious problem associated with acute and long-term lithium therapy is that of toxicity due to elevated lithium blood levels. Lithium has a low therapeutic index, and severe lithium toxicity can cause permanent renal and neurologic damage, as well as death. Though initial signs and symptoms of toxicity usually do not manifest until blood levels are above 1.5 mEq/L, tolerability varies among patients and some individuals will be symptomatic at lower blood levels. The risk of lithium toxicity can be reduced by a number of basic steps. Patients and family members must be aware of the signs of lithium toxicity: dizziness, clumsiness, unsteady gait, slurred speech, coarse tremors, abdominal pain, vomiting, sedation, confusion, and blurry vision. Basically, the subject intoxicated with lithium looks and acts like a “drunk” person and in these cases a stat lithium level is indicated. If a patient has difficulty with taking fluids or has excessive fluid loss (nausea, vomiting, diarrhea, febrile illness), lithium doses should be reduced or temporarily held until regular fluid intake is maintained. If other symptoms of lithium toxicity occur in addition to gastrointestinal distress, referral for immediate evaluation is necessary.

The dose escalation of lithium should be conservative, especially in outpatient settings, and blood levels should be obtained as early as 6 to 7 days after each dose increase, if the mood symptoms are recurring (e.g., check adherence), and immediately if clinical symptoms of toxicity occur. Patients should be counseled to maintain adequate hydration during vigorous exercise or on hot days, and avoid

major changes in salt, caffeine, or fluid intake. In addition, they must notify physicians and pharmacists that they are taking lithium, and do not take substances that interact with lithium. Common conditions and nonprescription drugs and substances that can elevate lithium levels include dehydration, diuretics, most nonsteroidal anti-inflammatory drugs (not acetaminophen), and alcohol. Caffeine tends to lower lithium levels. The list of prescription drugs that interact with lithium is long and should be checked prior to prescribing any new medication.

Lithium has a number of different potential side effects associated with short- and long-term treatment, which may be particularly bothersome to youth (acne, increased weight, tiredness, polyuria, poor concentration and "dullness," and rarely hair loss) (see Table 5.4.2.6). Patients have a wide range of tolerability to lithium, with some having minimal or manageable side effects while others will have significant problems. Sometimes side effects can be ameliorated by dose reduction or by switching between extended release and immediate release preparations and/or dividing the dose during the day.

Two issues that require ongoing monitoring are the potential for kidney damage and hypothyroidism. Lithium inhibits the renal tubular response to antidiuretic hormone, which decreases the ability to concentrate urine and leads to polyuria. Evidence from biopsy studies in adults indicates that in some cases lithium can lead to chronic interstitial nephritis (119,160–162). However, selection bias and the fact that similar changes have been found in adult psychiatric patients who have not been treated with lithium make it difficult to determine how much lithium treatment elevates the risk of kidney damage (160). Studies of the effects of lithium on glomerular function have generally showed minimal to mild reductions associated with long-term treatment. These data have made it difficult to know how to monitor for the undetermined but likely low risk of developing clinically significant kidney damage. A conservative monitoring approach is noted in Table 5.4.2.7. The decision to refer for renal consultation and/or discontinue lithium treatment remains one of clinical judgment, though a significant change in serum creatinine should trigger a thorough evaluation.

TABLE 5.4.2.6

LITHIUM SIDE EFFECTS

Common	Polyuria, polydipsia, tremor, weight gain, nausea, diarrhea, hypothyroidism, cognitive dulling, sedation, leukocytosis
Uncommon	New onset or exacerbation of acne or psoriasis, bradycardia, hair loss, ECG changes (T-wave flattening)
Rare	Kidney, brain damage and death (due to acute toxicity), decreased renal function, pseudotumor cerebri, extrapyramidal symptoms, movement abnormalities, nystagmus, seizure, hyperparathyroidism, sinus node dysfunction, arrhythmias

TABLE 5.4.2.7

ROUTINE LABORATORY MONITORING BEFORE AND DURING PHARMACOTHERAPY

Medication	Baseline Tests	Follow-up	Test Frequency[a]	Comments
Lithium	BUN, creatinine, TSH, free T4, urinalysis, CBC, electrolytes, calcium, albumin, height, weight, BMI	Lithium level BUN, creatinine, TSH, free T4, urinalysis, calcium, albumin, height, weight, BMI	Each dose change and q3–6mo q3–6mo	24-hr urine for protein and creatinine clearance if marked polyuria, proteinuria, or change in serum creatinine
Valproate	CBC with differential and platelet count, AST, ALT, lipase, height, weight, BMI menstrual history	Valproate level and platelet count, AST, ALT Height, weight, BMI, menstrual history	q2wk × 2, then q month × 2, then q3–6mo and with each dose change Each appointment	Risk of hepatic failure is highest in first 6 mo of treatment. Repeat lipase if pancreatitis suspected
Carbamazepine	CBC with differential and platelet count, AST, ALT, sodium	Carbamazepine level, CBC with differential and platelet count, AST, ALT, sodium	1 and 3–4 wks after dose change and then q3–6mo	Check labs if unexplained fever, sore throat, lymphadenopathy, or severe fatigue
Antipsychotics	Glucose, triglycerides, total cholesterol, HDL, LDL, AIMS, height, weight, BMI For ziprasidone EKG	Glucose, triglycerides, total cholesterol, HDL, LDL AIMS Height, weight, BMI EKG as necessary	3 mo after start, then q6–12mo q3–6mo Every appointment	Check metabolic status if substantial weight gain

Note: A pregnancy test should be performed in all postmenarchal females at baseline and whenever pregnancy is a possibility over follow-up.

[a]Follow-up tests should be performed whenever clinical symptoms of serious side effects occur.

BMI, body mass index; BUN, blood urea nitrogen; TSH, thyroid-stimulating hormone; AST, aspartate aminotransferase; ALT, alanine aminotransferase; CBC, complete blood count; HDL, high-density lipoprotein; LDL, low-density lipoprotein; AIMS, Abnormal Involuntary Movement Scale; EKG, electrocardiogram.

Lithium inhibits the effect of thyroid-stimulating hormone (TSH) in the thyroid gland. As a consequence, approximately 25% of youth develop elevated TSH levels within 3 months of initiating lithium treatment (163). The long-term effects on the thyroid have not been determined in a pediatric population, and TSH levels can be just transiently elevated in BP adults initiating lithium treatment (162). Given the developmental implications, clear hypothyroidism induced by lithium in youth will require intervention. Whether to treat or discontinue lithium in patients with subclinical hypothyroidism is less clear. However, if lithium is clearly helping the

individual, thyroid replacement treatment is indicated.

Preliminary evidence of greater mood instability and depression in BP adults with lower levels of free T4 or higher levels of TSH at baseline or during treatment with lithium indicates that adding thyroid hormone may be reasonable (162,164,165). Although not well studied, lithium can also cause hyperparathyroidism and as a consequence abnormalities in calcium, phosphorus, and magnesium blood levels.

Finally, lithium has been associated with cardiac abnormalities in the fetus when administered during the first trimester of pregnancy. Therefore, the continuation of lithium during this period of pregnancy needs to be balanced against the possibility of a manic recurrence with the deleterious consequences for the mother and the fetus.

Valproate

Valproate has gastrointestinal, neurologic, hematologic, and cognitive side effects that usually can be minimized by careful titration or dose reduction (Table 5.4.2.8). Periodic blood tests are often performed in order to monitor for the rare but serious side effects (hepatic failure, pancreatitis, thrombocytopenia) (Table 5.4.2.7) (116). It is very important that patients and family members are aware of the initial symptomatic presentations of these side effects and know to obtain an urgent assessment if they occur. For instance, hepatotoxicity can present with symptoms of vomiting, nausea, anorexia, lethargy, drowsiness, and facial edema. Mild elevations of serum transaminases do occur during treatment and are of questionable clinical significance unless they are more than three times the normal level. The risk of hepatic failure is most elevated in children under the age of 3, in those who have metabolic or neurologic disorders, and those who are taking multiple anticonvulsants.

Although uncertain, valproate has been associated with polycystic ovarian syndrome. Thus, baseline menstrual history and a gynecologic consultation of any female who develops significant changes in her menstrual cycle and/or hirsutism while on this medication are warranted. Valproate has been associated with spina bifida in fetuses exposed to this medication during the first trimester of pregnancy. As with lithium, the clinician needs to consider the benefits and risks of continuing valproate during the pregnancy. If valproate is going to be continued, some advocate for the use of folic acid as preventative against neurologic problems in the fetus.

TABLE 5.4.2.8

VALPROATE SIDE EFFECTS

Common	Weight gain, tremor, nausea, diarrhea, cognitive dulling, sedation, fatigue, ataxia, dizziness
Uncommon	Serum transaminase elevations, alopecia, elevated testosterone, polycystic ovarian syndrome, rash, hair loss
Rare	Hepatic failure, thrombocytopenia, pancreatitis, severe dermatologic reactions,

	myelosuppression, anticonvulsant hypersensitivity syndrome

TABLE 5.4.2.9

CARBAMAZEPINE SIDE EFFECTS

Common	Nausea, vomiting, clumsiness, dizziness, nystagmus, sedation, blurred vision, diplopia, cognitive dulling, ataxia, photosensitivity CYP450 enzyme induction (increased clearance of drugs metabolized by hepatic cytochrome system, including oral contraceptives)
Uncommon	Hyponatremia, rash, confusion, leukopenia
Rare	Serious dermatologic reactions, agranulocytosis, aplastic anemia, atrioventricular block, arrhythmias, hepatitis, renal dysfunction, anticonvulsant hypersensitivity syndrome

Carbamazepine

As with valproate, carbamazepine has neurologic, cognitive, and gastrointestinal side effects that can usually be managed by dose adjustment, as well as rare serious side effects that are difficult to prevent via routine blood monitoring (Tables 5.4.2.7 and 5.4.2.9) (116). Decreases in platelet and white blood cell counts are not uncommon during carbamazepine treatment, but they do not necessarily predict subsequent development of aplastic anemia or agranulocytosis. Carbamazepine does induce its own metabolism, as well as other drugs that are metabolized by the hepatic cytochrome P450 1A2 and 3A4 isoenzymes. Therefore, blood levels must be repeated several weeks after dose changes and care must be taken when other medications are coadministered (such as oral contraceptives), as they may not reach therapeutic levels. A metabolite of carbamazepine, oxycarbamazepine, does not have the hematologic side effects associated with the parental compound. However, it seems that this medication is not efficacious for the treatment of BP (138).

Lamotrigine

The neurologic and cognitive side effects of lamotrigine seem similar to other anticonvulsants, and are usually managed by dose adjustment (see Table 5.4.2.10). Lamotrigine can induce rash in about 1/2,500 youth. This rash is reversible if lamotrigine is discontinued, but in some cases it may progress to a serious dermatologic reaction such as Stevens–Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN). Though rare, these reactions are more common in youth than adults, and it is difficult to predict whether a rash will progress to SJS or TEN. Therefore, unless a new rash is clearly attributable to something other than lamotrigine, treatment should be suspended. The rate of serious dermatologic reactions may be reduced by current dosing recommendations that prescribe small and gradual dose escalation, in particular with the concomitant use of valproate.

TABLE 5.4.2.10

LAMOTRIGINE SIDE EFFECTS

Common	Dizziness, ataxia, headache, tremor, blurred vision, diplopia
Uncommon	Rash, nausea, vomiting, ataxia, cognitive dulling, confusion
Rare	Serious dermatologic reactions, anemia, anticonvulsant hypersensitivity syndrome

TABLE 5.4.2.11

ATYPICAL ANTIPSYCHOTIC SIDE EFFECTS

Common	Weight gain,[a] postural hypotension, extrapyramidal symptoms,[a] dizziness, sedation[a]
Uncommon	Hyperglycemia, diabetes, hypercholesterolemia, increased triglycerides, hyperprolactinemia,[a] rash, photosensitivity, nausea, diarrhea, dyspepsia, constipation, elevated serum transaminases, urinary difficulties, sexual dysfunction, cognitive dulling
Rare	Tardive dyskinesia, neuroleptic malignant syndrome, seizure, hepatic failure

[a]Rate of side effect may vary substantially among the different atypical antipsychotics.

Atypical Antipsychotics

The atypical antipsychotics have some differences in side effect profiles, though there are some side effects that are common to all of them in varying degrees (Table 5.4.2.11). In general, there has been increasing concern about the metabolic effects (e.g., increased weight, glucose, and lipids) of some of these medications, which are of substantial concern when these agents are used in children and adolescents over extended periods of time (125,166–168). Routine monitoring parameters have not been established, but it is recommended to measure the child's body mass index (BMI) and fasting glucose and lipids before and routinely (every 6 months and whenever clinical symptoms indicate) while taking these medications (Table 5.4.2.7). If a patient exhibits significant weight gain, it should prompt a more thorough investigation of metabolic status and a reevaluation of the risk–benefit ratio of continuing the current atypical antipsychotic.

Although much less often than the typical antipsychotics, the atypical antipsychotics may cause extrapyramidal symptoms, tardive dyskinesia, and neuroleptic malignant syndrome; thus, it is necessary to evaluate the child at baseline and routinely over follow-up for abnormal movements. Finally, the long-term side effects including chronic hyperprolactinemia associated with the atypicals, particularly risperidol, have not been well studied.

MONITORING PHARMACOTHERAPY

Although the medications that are used to treat bipolar disorder have the potential for significant side effects, there is no evidence whether routine laboratory monitoring

reduces the risk of adverse events. Table 5.4.2.8 gives general monitoring guidelines based on recommendations from Federal Drug Administration (FDA) package inserts and typical practice from our BP research centers. It does not have empirical support and is not a substitute for clinical judgment. In many cases, the benefits of treatment outweigh potential risks even if regular laboratory monitoring is not feasible for a patient. Laboratory tests are not a replacement for clinical evaluation, and it is important to review signs and symptoms of potential adverse events with patients and their families as well as emphasize the need to contact the prescribing physician if these symptoms occur.

MANAGEMENT OF COMORBID DISORDERS

It is crucial to treat accompanying comorbid disorders, because they may worsen the prognosis of BP (23,169,170). However, most of the existing literature regarding the treatment of comorbid disorders in BP youth is anecdotal or from open-label studies. For ADHD, few RCTs with small samples have suggested that adding stimulants is beneficial and safe (171,172).

In general, it is recommended to use the best available medications and/or psychosocial treatments for each specific comorbid disorder (see respective chapters in this book). It is important to begin treatment for each comorbid disorder sequentially. Also, since some medications may cause mood dysregulation, if appropriate, psychosocial treatments should be tried before adding new medications (e.g., CBT for anxiety disorders). For BP youth with certain comorbid psychiatric or medical conditions, sometimes the use of medications for BP may also target the other disorder (valproate for BP and seizures).

For youth with dubious diagnosis of BP, it is better to treat first the other disorder and reevaluate for the presence of mood symptoms. In particular, this is relevant to ADHD because of the stimulants' rapid action. However, for youth with clear BP, before treating the comorbid disorder(s), it is recommended first to stabilize the symptoms of BP. Likewise, if the child's "comorbid" symptoms (hyperactivity, behavior problems) appear to be secondary to the mood disorder (mania, depression, or both), it is also recommended first to treat the BP. If the symptoms of BP improve and the other symptoms persist, treatment for both the BP and the comorbid conditions is indicated.

SUMMARY AND FUTURE DIRECTIONS

BP is a recurrent familial disorder that frequently emerges early in life and is associated with significant morbidity and sometimes mortality due to suicide. Pediatric BP usually follows an ongoing changeable and sinuous course, with

patients having a wide spectrum of mood symptoms that can range from mild to severe depression, mania, and/or hypomania. These results explain, at least in part, the difficulties encountered when treating youth with BP spectrum disorders. Furthermore, it is likely that the very rapid fluctuation in mood symptoms, combined with the developmental issues influencing the clinical picture of BP youth, the difficulties children and adolescents have verbalizing their emotions, and the high rates of comorbid disorders, account for the complexity and current controversies in diagnosing BP youth.

As reviewed in this chapter, it is clear that youth may manifest classical symptoms of BP. However, many youth do not fulfill the current DSM BP-I or II criteria for the diagnoses mainly because they lack the required duration of symptoms. Moreover, many youth referred for evaluation for BP have severe mood lability, "affective storms," irritability, verbal and/or physical aggression, and ODD- and ADHD-like symptoms. These youth may have BP, but careful longitudinal follow-up is mandatory to ascertain whether these symptoms are indeed manifestations of BP, prodromal symptoms for more classical manifestations of BP, the symptoms of non-BP disorders (e.g., MDD, DBD, anxiety), reactions to ongoing environmental factors (e.g., bullying, abuse, family conflicts), or indicate that these youth have other difficulties regulating their mood.

The enduring and rapid changeability of symptoms of BP in youth from very early in life and at crucial life stages deprive them of the opportunity for normal, emotional, cognitive, and social development. Moreover, this illness can negatively affect relationships with parents and siblings, and family finances. Thus, early recognition and acute and maintenance treatment of BP in children and adolescents are of utmost importance to ameliorate ongoing syndromal and subsyndromal symptomatology and to reduce or prevent the serious psychosocial morbidity that can accompany this illness.

The existent pharmacologic studies suggest that the atypical antipsychotics followed by the mood stabilizers, and their combination are helpful for the acute treatment of manic/mixed symptoms. However, studies of longer duration are warranted. Also, further pharmacologic and psychosocial acute and maintenance RCTs to reduce the risk of relapse and recurrences as well as examine the effects of development, comorbid disorders, family environment, and parental psychopathology on treatment response, and the long-term side effects of pharmacologic treatments in youth are urgently needed.

Future studies evaluating possible preventative strategies for youth at high risk for BP, especially offspring at very high risk to develop BP are indicated. Also, studies to evaluate and analyze the contributions of risk and protective factors (e.g., cognitive development, social and coping skills, environmental factors to outcome are warranted. Regarding the environmental factors, important issues such as parental lifetime and current psychopathology, support, exposure to negative events (abuse,

poor school or neighborhoods, and ongoing family conflicts) should be considered.

Finally, genetic and other biologic studies including pharmacogenetic and further studies correlating the effects of treatment and biochemical changes on the brain are warranted.

ACKNOWLEDGMENTS

This work was supported in part by NIMH grants MH59929, MH60952, and MH100056. The authors would like to thank Rita Scholle for her assistance with manuscript preparation and Andrès Martin for carefully reviewing the manuscript.

CHAPTER 5.4.3 ■ CHILD AND ADOLESCENT SUICIDAL BEHAVIOR

CYNTHIA R. PFEFFER

INTRODUCTION

Recent research with diverse methods expanded knowledge of child and adolescent suicide risk, treatment and prevention; but suicidal ideation and attempts among these populations continue to increase. DSM-5 described suicidal behavior and nonsuicidal self-injury as "Conditions for Further Study," indicating that "future research is encouraged" (p. 783) (1). The 2012 National Strategy for Suicide Prevention outlined comprehensive suicide prevention strategies (2). This chapter, based primarily on empirical investigations, presents an overview of suicidal behavior to assist clinicians and US public policy developers to prevent suicidal morbidities and fatalities among young populations.

EPIDEMIOLOGY

The 2014 US suicide data highlight suicide as a public health problem, particularly for adolescents, youth, and middle age adults (3). Suicide, 10th leading cause of US deaths, occurred among 42,773 people indicating a 13.0 per 100,000 population death rate, accounting for 1.6% of all deaths and a 24% higher rate than in 1999 (10.5 per 100,000). Unintentional deaths are the leading cause of death for ages 1 to 44 years. Suicide is the second leading cause of death for ages 10 to 24 years. Suicide occurred among 425 children, aged 10 to 14 years, accounting for a 2.1 per 100,000 death rate and 14.7% of all deaths in this age group. Suicide occurred among 5,079 adolescents and young adults, aged 15 to 24 years, accounting for a 11.6 per 100,000 death rate and 17.6% of all deaths in this age group. Homicide is the third leading cause of death for ages 1 to 4 and 15 to 24 years, fourth for ages 5 to 9 years, and fifth for ages 10 to 14 years.

Number of suicide deaths and percent of all deaths were higher for males, aged 10 to 14 years (males: 275, 15.5%; females 150, 13.4%) and 15 to 24 years (males: 4,089, 19.4%; females: 990, 12.9%). Female suicide rates for ages 10 to 14 years, compared to other ages, had the highest increase (200%), tripling from 0.5 in 1999 to 1.5 per 100,000 in 2014.

Suicide was the second leading cause of death among Whites and American Indians/Alaskan Natives, aged 10 to 14 accounting for 347 (16.8%) and 12 (2.8%) deaths, respectively, and for ages 15 to 24 years accounting for 4,177 (20.1%) and 129 (2.5%) deaths, respectively. It is the third leading cause of death among

Hispanics aged 10 to 14 and 15 to 24 years, accounting for 66 (11.3%) and 719 (14.7%) deaths, respectively. Suicide among Blacks aged 15 to 24 years and 10 to 14 years is the third and the fourth leading cause of death, respectively, accounting for 544 (8.2%) and 56 (8.4%) suicides, respectively.

Use of firearms was the most common suicide method followed by suffocation for individuals older than 14 years. Suicide method rates for ages 15 to 24 years were firearms (44.7%), suffocation (39.6%), poisoning (7.1%), fall (3.3%), other classifiable (2.4%), and drowning, fire, transportation, unspecified (1.0%). Suicide method rates for ages 10 to 14 years were suffocation (52.9%), firearms (40.9%), poisoning (4.2%), and other classifiable and fall, transportation unspecified (1.0%).

Figure 5.4.3.1 shows annual US suicide rates per 100,000 population for both sexes and all races from 1999 through 2014 for specific age groups (3).

Suicide rates increased almost each year beginning at rate 13.9 in 1999 for ages 45 to 54 years, in 2005 at rate 13.7 for ages 55 to 64 years, and in 2005 at rate 11.0 for all ages. Suicide increased for younger ages almost yearly in 2007 at rate 9.6 for ages 15 to 24 years, in 2009 at rate 13.1 for ages 25 to 34 years, and in 2011 at rate 0.7 for ages 5 to 14 years. Notably, annual suicide rates for ages 45 to 54 years since 2007 surpassed those for all age groups and are attributed to White non-Hispanic men and women, lower educational level, declined mental and physical health, inability to work and conduct daily activities, chronic pain, and economic insecurity due to job and income loss, but not to a simple cohort effect (4). These suicide rates may have implications for increasing suicide among children, adolescents and young adults, who suffered adverse childhood experiences.

The National Youth Risk Behavior Survey (YRBS), completed during springtime every 2 years since 1991 by a US representative sample of 9th through 12th graders in public and private high schools, documented that during the 12 months before the 2015 survey 17.7% adolescents seriously considered attempting suicide, 14.6% developed a suicide attempt plan, 8.6% attempted suicide, and 2.8% attempted suicide resulting in injury, poisoning, or overdose that necessitated treatment (5). Figure 5.4.3.2 indicates YRBS suicidal ideation and attempt rates from 1991 through 2015. From 1991 through 2009, significant decreases occurred for suicidal ideation rates and significant increases occurred after 2009 through 2015; no significant suicide attempt rate changes occurred from 2009 through 2015.

YRBS documented firearm accessibility: 5.3% adolescents reported carrying a gun at least 1 day during the 30 days before the 2015 survey, accounting for a significant decrease since 1997 (7.9%) (4). Rates were higher for males (8.7%) than females (1.6%) and for White (9.6%), Black (9.6%), and Hispanic males (6.5%) than White (1.4%), Black (1.7%), and Hispanic females (1.9%).

CLINICAL DESCRIPTION

DSM-5 criteria provide “a common language for researchers and clinicians who are interested in studying these disorders” but “the proposed criteria are not intended for clinical use” (p. 783) (1). Suicidal behavior disorder criteria include “within the last 24 months, the individual has made a suicide attempt … set of actions would lead to his or her own death … does not meet criteria for nonsuicidal self-injury … not applied to suicidal ideation … not initiated during a state of delirium or confusion … not undertaken solely for a political or religious objective” (p. 801) (1). Nonsuicidal self-injury criteria include “in the last year, the individual has, on 5 or more days, engaged in intentional self-inflicted damage to the surface of his or her body of a sort likely to induce bleeding, bruising, or pain … expectation that the injury will lead to only minor or moderate physical harm … to obtain relief from a negative feeling or cognitive state, to resolve an interpersonal difficulty, to induce a positive feeling … preoccupation with the intended behavior that is difficult to control, thinking about self-injury that occurs frequently … behavior is not socially sanctioned … causes clinically significant distress … does not occur exclusively during psychotic episodes, delirium, substance intoxication or substance withdrawal … not part of a pattern of repetitive stereotypies, not better explained by another mental disorder or medical condition” (p. 803) (1).
FIGURE 5.4.3.1. US suicide rates per 100,000 population from 1999 through 2014 for specific age groups.

Child and adolescent suicidal conditions comprise a continuum from self-harm

ideas with intent to die, ideas to plan suicide, suicide attempt, and suicide (6).

RISK FACTORS FOR SUICIDAL IDEATION AND ACTS

Primary Psychiatric Disorders among Youth Suicide Victims

Psychological autopsy studies utilize information from coroner reports and direct interviews of suicide victims' relatives to identify psychosocial suicide risk factors. First child and adolescent psychological autopsy study involved all suicides in England and Wales in 1962–1068 (30 children: 21 males, 9 females), aged 12 to 14 years (7). Most common suicide method was carbon monoxide (43%). Forty-six percent reported prior suicidal ideation or acts, 57% had mixed antisocial, affective symptoms, 36% experienced recent disciplinary crisis, and 55% parents suffered emotional symptoms requiring treatment. Subsequent child and adolescent psychological autopsy studies indicated approximately 90% had a psychiatric disorder and 70% had comorbid psychiatric disorders at time of suicide (8,9). Prior suicide attempt increased suicide risk 51- to 89-fold (8,9). Majority (61% to 76%) of youth suicide victims suffered from mood disorders increasing suicide risk 8- to 13-fold. Major depressive disorder (MDD) prevalence ranged from 32% to 54%, increasing suicide risk 27-fold. Current substance abuse disorder, occurring in 27% to 62%, increased suicide risk 8.5-fold. Other disorders were bipolar disorder (20%), increasing suicide risk 9-fold, and anxiety disorders (27%), eating disorders (4%), and schizophrenia (4%) (8). Suicide victims without psychiatric disorders had high prior suicide ideation or attempt rates, low suicide intent, easy access to firearms, and disciplinary problems (10).

Suicide Ideation and Attempts, Nonsuicidal Self-Injury, and Psychopathology

Predicting risk for transitions between suicidal states is an important suicide prevention strategy. National Comorbidity Survey Replication Adolescent Supplement reported 33% suicide ideators developed a suicide plan, 60.8% with a plan and 20.4% without a plan attempted suicide; indicating that 60% of first suicide attempts are planned (11). Transitions from suicide ideation to plan (63.1%) and ideation to attempt (86.1%) occurred in first year of suicidal ideation onset. Only MDD predicted a suicide plan among those with suicidal ideation. Transitions from ideation to attempt were associated with MDD, eating disorder, attention-deficit hyperactivity disorder, conduct disorder, and intermittent explosive disorders.
FIGURE 5.4.3.2. High school student suicidal ideation and suicide attempt rates from 1991, 2009, 2011, 2015.

A prospective study of 506 adolescents participating in a school-based suicide screening program identified that adolescents, who had serious repeated suicidal ideation, attempted suicide during 4- to 6-year follow-up (12). Earlier attempts were predicted by proximal suicidal ideation lasting greater than 1 hour. Other prospective research suggested developmental transitions affect suicidal risk; child psychiatric inpatients with suicidal ideation were at 4-fold and those who attempted suicide were at 6-fold increased suicide attempt risk in adolescence (13). Highest risk period was first year after discharge. Strongest predictor of adolescent suicide attempt was number of prior suicide attempts rather than a mood disorder alone; mood disorder with suicide attempt history predicted future attempts (14). Psychomotor agitation and alcohol and substance abuse increase suicide attempt lethality (15).

Inability to make decisions that provide rewarding experiences may be a cognitive suicide attempt risk factor among adolescents with MDD (16). A study of depressed adolescents suggested that suicide attempters versus suicide ideators, had more severe anhedonia and were less likely to pursue rewards during an experimental computer task, when outcomes were uncertain (17). These results imply that intense adverse emotions impair cognitive decision-making processes to integrate prior rewarding experiences when making present decisions.

Chronic nonsuicidal self-injury is among the strongest predictors for suicide (18)

and suicide attempts (19) and stronger than depression, anxiety, borderline personality disorder, and impulsivity (19,20). The Avon Longitudinal Study of Parents and Children, utilizing 4,855 adolescents, identified that self-injuring adolescents with suicidal intent compared to without suicidal intent had 3.5-fold higher risk for depressive and anxiety disorders (21).

Adolescent nonsuicidal self-injury risk was associated with family dysfunction, poor parental mental health, insecure attachment, and temperamental characteristics that diminish emotion regulation, self-confidence, and problem-solving skills (22). An experimental study identified that self-injuring adolescents, compared to healthy controls, showed poorer inhibition to images depicting negative emotional content; implying that nonsuicidal self-injuring adolescents have more difficulty maintaining cognitive behavioral control when faced with negative emotional stimuli (23).

Bipolar disorder is among the most lethal diagnoses. A longitudinal study of 405 children and adolescents with bipolar disorder I, II, and NOS found 33% had history of a suicide attempt (24). Prevalent suicide attempt predictors were mixed bipolar episodes, severe depression, psychosis, self-injury, Panic and substance use disorders, psychiatric hospitalization, and family history of depression.

Psychosis is a prominent risk factor for suicide attempts. A prospective study of 110 children and adolescents with first-episode psychosis indicated suicide attempt prevalence was 12.4% at 24-month reevaluation (25). Two independent case-controlled studies of 212 adolescents, aged 11 to 13 years, and 211 adolescents, aged 13 to 15 years, attending school suggested psychotic symptoms were associated with 10-fold increased risk of suicidal ideation, plans or acts; but risk increased to 14-fold when adolescents were also depressed (26). Adolescents with suicidal ideation with, compared to without, psychotic symptoms had a 20-fold increased risk of suicide plans and attempts. Evaluating psychotic symptoms is essential during suicide risk assessment.

A consistent research finding is that comorbid anxiety and depression significantly increases risk for proximal suicidal attempts in children and adolescents (27). Posttraumatic stress disorder (PTSD) comorbid with MDD mediated the link between traumatic events and suicidal ideation and acts (28). This study suggested rates of suicidal ideation (30% to 80%) and suicide attempts (15% to 50%) in adolescents with PTSD were similar to rates in depressive disorders and schizophrenia. A longitudinal study of 613 children recruited in first grade and followed up in 10th grade suggested a predictor of 10th grader suicidal ideation involved interaction between 10th grader depressive symptoms and first grader anxiety sensitivity to cognitive concerns (i.e., fears of experiencing anxiety or panic from onset of cognitive concerns, such as depersonalization, racing thoughts, lack of concentration) (29). This study suggested a process that early-onset anxiety sensitivity amplified depression distress to promote risk for suicidal ideation.

Few studies examined relations between suicidal ideation and specific anxiety

disorders. A study of 54 child and adolescent outpatients with obsessive compulsive disorder (OCD) found 13% had suicidal ideation, which was associated with OCD-specific symptoms, such as symmetry/ordering, sexuality/religiosity, need to tell, confess, or ask, and depressive and anxiety symptoms, age, and functional impairment (30). A longitudinal study of 144 female (72%) adolescent psychiatric inpatients suggested significant direct relationship between social anxiety disorder at hospitalization and suicidal ideation at 18-month follow-up, and significant indirect effect on suicidal ideation at 18-month follow-up through loneliness at 9-month follow-up (31). The study highlighted loneliness related to social anxiety as risk factor for adolescent suicidal ideation.

Personality Disorders and Traits

Psychological autopsy studies suggested 33% youth suicide victims suffered from a personality disorder, especially borderline and antisocial personality disorders (32) and narcissistic and schizoid traits (33). Among 366 adolescents with repeated self-harm, 60% suffered from a personality disorder and over 1-year follow-up had severe self-harm, suicide attempts, depressive symptoms, and functional impairment (34). Other studies suggested personality traits, such as extreme self-reliance for solving problems or high sensation-seeking behavior, were associated with suicidal ideation and attempts (35,36). Identifying adolescent personality traits is important to suicide prevention.

MINORITY SEXUAL ORIENTATION AND SUICIDAL IDEATION AND ACTS

The National Longitudinal Study of Adolescent Health reported adolescents with minority sexual orientation, compared to other adolescents, had higher risk for suicidal ideation and attempts, depression, hopelessness, alcohol abuse, victimization, and recent family or peer suicide attempts (37). The New Zealand Birth Cohort Study documented that by age 21 years, 2.8% of 1,007 participants were classified as gay, lesbian, or bisexual and exhibited more suicidal ideation and attempts, major depressive, generalized anxiety, and conduct disorders (38).

ADVERSE CHILDHOOD EXPERIENCES

Children and adolescents with history of suicidal ideation, attempts, or suicide often experienced cumulative adverse experiences (39,40). A longitudinal study of a national sample of 1,186 children and adolescents suggested suicide ideation risk was greater among those experiencing recent peer victimization (2.4-fold), sexual

assault (3.4-fold), and parental maltreatment (4.4-fold); but exposure to seven or more recent types of victimization increased likelihood for suicidal ideation (6-fold) (41). A case-control longitudinal study using Danish register data of 403,321 children and adolescents of whom 0.8% (3,465 individuals) attempted suicide described a multiplicative dose–response relationship between risk of suicide attempts and number of exposures to parental adverse events including low family income, parental psychiatric illness, suicide attempt, and suicide (42). Another longitudinal Danish register study of 3,465 suicide attempters, aged 10 to 22 years, and 75,300 matched controls described a significantly higher suicide attempt rate for those bereaved by a biologic parental death, but it doubled with a second biologic parental death (43).

Family history of suicide imparts for adolescent girls and boys, a 3- and 5-fold greater suicide risk, respectively, than those in the community (44). Risk for youth suicide is transmitted in families independent of psychiatric disorders and mediated by the transmission of impulsive aggression (45). A prospective study suggested parental suicide attempts had a direct predictive effect on adolescent offspring suicide attempt in addition to risk effects of offspring mood disorder and impulsive aggression (46). Evaluating youth after family suicidal behavior is an important suicide prevention strategy.

Youth suicides and nonfatal suicide attempts sometimes occur in the context of time-space clusters stimulated by mechanisms of imitation of suicidal peers and exposure to suicide presentations on news, fictional or social media (47,48). Cultural affiliation problems related to migration and changing social supports among Black, American Indian, Alaska Native, and Native Hawaiian adolescents significantly predicted adolescent suicide attempts (49–51). Community education about suicide prevention is essential when a child or adolescent commits suicide or feels socially isolated.

Physical problems near time of birth, including respiratory distress for more than an hour after birth, no antenatal care before 20 weeks of pregnancy, chronic maternal physical disease and chronic childhood medical illnesses, such as diabetes and epilepsy, are associated with increased risk for suicidal behavior (52–54). Inquiry about medical problems is essential for youth suicide risk assessment.

Neurobiologic Factors

Serotonin neurotransmitter system dysregulation, manifest as low levels of whole blood tryptophan (55) or affected by interactions between early environmental stress and the short(s) allele of the serotonin transporter gene (56,57), increase risk for child and adolescent suicidal attempts and nonsuicidal self-injury. Suicide risk may involve more complex interactions between a specific genotype and environmental adverse event exposure during a critical window of brain development (58).

Early-life adversity was associated with HPA axis dysregulation caused by epigenetic effects involving DNA methylation that affects expression of hippocampal glucocorticoid receptor variants in adult suicide victims (59). HPA axis dysregulation was reported as elevated blood post dexamethasone cortisol levels among child suicide attempters and elevated baseline blood cortisol levels before sleep onset of adolescent suicide attempters (60,61). A differential pattern of higher cortisol secretion in response to a serotonergic agonist, meta-chlorophenylpiperazine (mCPP), was shown for adolescent depressed male suicide attempters compared to suicidal and nonsuicidal depressed females (62). A prospective study of 138 adolescent females, at risk for suicidal behavior and exposed at baseline to a psychosocial stress task, assessed salivary cortisol levels and suicidal ideation obtained pre- and post-stressor (63). HPA axis hyperresponsive females, compared to normal or hyporesponsive females, were more likely to report lifetime history of suicidal ideation at baseline and more likely to have suicidal ideation 3 months after baseline, compared to normal females. Adolescents with nonsuicidal self-injury, compared to healthy controls, and exposed to an experimental cold pain reported greater pain threshold, pain tolerance, and lower pain intensity, which was associated with heightened reactivity of the HPA axis and autonomic nervous system (64).

Extensive adolescent brain maturation highlights the importance of studying brain structure and functioning and relates these to adolescent suicidal behavior. Magnetic resonance imaging (MRI) identified that adolescents with MDD and suicide attempt history had elevated brain white matter hyperintensities (65). Functional brain magnetic resonance imaging (fMRI) of depressed adolescents with and without suicide attempt history suggested adolescent suicide attempters had elevated activity in attention control circuitry and reduced anterior cingulate–insula functional connectivity when responding to 50% intensity angry faces but no evident differences when emotional stimuli were absent (66). This study suggested markers of past suicide attempt may be abnormal functioning in the salience and attention neural circuitry when processing emotional stimuli but normal network functioning in the absence of emotional stimuli. Functional neuroimaging with cold as a pain stimulus was studied among adolescents with, compared to those without, nonsuicidal self-injury (67). Those with nonsuicidal self-injury had greater blood oxygenation level–dependent (BOLD) response in right midbrain/pons, culmen, amygdala, and parahippocampal, inferior frontal and superior temporal gyri, and orbital frontal cortex. These brain regions are associated with reward and pain processing in dopamine and opiate systems. The results suggested associations between pain and reward among nonsuicidal self-injuring adolescents.

Sleep disturbances including insomnia, shortened sleep duration, hypersomnia, nightmares, and sleep-related serotonergic functioning and growth hormone secretion may predict adolescent suicidal ideation, suicide attempts, and suicide (61,68,69).

Immediate effects of sleep deprivation include mood instability, negative affect, and impulsivity in response to negative stimuli. Such symptoms increase risk for imminent suicidal ideation and attempts, especially for children and adolescents with mood and substance use disorders and psychosocial stresses. Sleep disturbances should be part of clinical suicide risk assessment.

RISK ASSESSMENT

Assessment of children and adolescents also involves parents to identify suicidal risk factors and plan for safety. Clinical interviews may be augmented with reliable and valid suicide risk rating scales, such as the Columbia-Suicide Severity Rating Scale measuring severity and intensity of suicidal ideation and lethality of suicide attempts and nonsuicidal self-injury (70). Self-report rating scales include Harkavy–Asnis Suicide Scale (71), Scale for Suicidal Ideation, Suicidal Intent Scale, Beck Depression Inventory, and Hopelessness Scale (72). Child Adolescent Suicide Potential Index (CASPI) measures risk related to recent suicidal ideation and attempts, psychiatric symptoms, and adverse childhood events (73). Implicit Association Test for Suicide Attempts or Nonsuicidal Self-Injury involves computerized measurement of adolescent reaction time to stimuli related to self and suicide or self-injury to predict future suicidal states (74).

TREATMENT

Acute Intervention

Review of randomized clinical trials to reduce child and adolescent suicidal ideation or attempts or self-injury suggested efficacy was strongest for interventions focusing on family interactions, other support, greatest number of sessions, motivational interviewing to enhance treatment compliance, and promotion of positive affect, sobriety, and healthy sleep (75). During psychiatric emergency intervention, a patient is not discharged until there is a safety plan derived from explicit discussion of suicidal intent, methods for maintaining safety, and no access to lethal suicidal methods (76). A randomized controlled emergency department intervention for adolescents at risk for suicidal behavior suggested motivational discussion and barrier-reduction to mental health services, compared to standard referral, significantly improved linkage to outpatient mental health services (77). A 12-week SAFETY cognitive behavioral family intervention integrated with emergency services focused on practicing skills to prevent repeated adolescent suicide attempts and increasing safety (78). It demonstrated significant decreased adolescent suicidal behavior, hopelessness, and parent depression 6 months after program entry.

Psychiatric hospitalization is recommended when safety is unpredictable and provides acute interventions and removal from a stressful environment. Outpatient and partial hospitalization treatments are utilized if low likelihood for imminent suicidal acts and presence of family support exist. A randomized controlled study comparing intervention as usual with an experimental collaborative care intervention including assessment of adolescent depression at initial meeting and during 12-month follow-up found significantly greater reduction in depressive symptoms for those in collaborative care; a program that increased patient motivation and reduced barriers for treatment (79).

Psychotherapy

Meta-analysis of 19 randomized controlled psychotherapeutic trials to reduce suicidal and nonsuicidal self-harm in 2,176 adolescents suggested lower self-injury rate for those in treatment (28%) compared to controls (33%) (80). Largest effects were for dialectical behavior therapy (DBT), cognitive behavioral therapy (CBT), and mentalization-based therapy (MBT). Another meta-analysis of 29 studies of child and adolescent cognitive behavioral, family, interpersonal, and psychodynamic interventions to reduce suicidal and nonsuicidal self-injury behaviors highlighted elements of efficacious treatments as family skills training to improve communication and problem solving, parent education in monitoring and managing, and child and adolescent skills training to regulate emotions and solve problems (81). Controlled treatment trials of DBT suggest total number of sessions is a partial mediator between treatment and changes in severity of suicidal ideation (82). DBT is an effective adjunct therapy for suicidal adolescents with bipolar disorder (83). Other effective therapies to reduce adolescent self-harm include attachment-based family therapy (ABFT) focusing on strengthening parent–adolescent attachment to create a protective and secure base for adolescent development, emotion regulation, and family cohesion (84) and MBT to improve self-awareness and reduced attachment avoidance (85).

Psychopharmacology

Many research methods are utilized to assess effects of psychopharmacological interventions for suicide risk. One method links large aggregated prescription data with suicide data from similar populations. Studies suggested that increased antidepressant prescription rates especially for selective serotonin reuptake inhibitors (SSRIs) were associated with lower suicide rates (86,87) and longer antidepressant drug treatment (180 vs. 55 days) reduced likelihood of suicide attempt (88).

Outcomes of depressed children and adolescents at risk for suicide were studied

in randomized, double-blind, placebo-controlled medication treatment studies. Treatment of Adolescent Depression Study (TADS), sponsored by NIMH, was a 36-week pharmacologic and psychotherapeutic treatment trial including 439 adolescents, aged 12 to 17 years, with MDD without high suicide risk (89). Initial acute 12-week randomized, double-blind, placebo-controlled phase compared efficacy of fluoxetine alone, CBT alone, combined CBT and fluoxetine, and placebo. After acute phase, all treatments were unblinded and nonresponders were discontinued from study, referred to community providers, but continued with study assessments to end of 36 weeks. Six-week consolidation phase involved acute phase responders beginning maintenance treatment in their assigned treatment and partial responders receiving 6 weeks in their assigned treatment with additional CBT or higher fluoxetine dose or both in the combined group. Eighteen-week continuation phase was long-term maintenance treatment. Final phase was a 1-year open community follow-up.

During 12-week acute phase, depression symptoms decreased in 71.0% with combined treatment, 60.6% with fluoxetine alone, 43.2% with CBT alone, and 34.8% with placebo (90). Suicidal ideation and attempts were rated by adolescents and study clinicians and reassessed by expert raters using the Columbia Classification Algorithm for Suicidal Assessment (91). At baseline, 29% reported suicidal ideation, which improved with each treatment but was greatest for combined CBT and fluoxetine treatment. Suicide-related events (suicidal ideation or attempts) during 12-week study included 10 (9.2%) adolescents in fluoxetine treatment, 5 (4.6%) in combined treatment, 5 (4.6%)in CBT, and 3 (2.7%) in placebo group. Only fluoxetine, compared to placebo, had significantly greater (2-fold) suicide-related events. A 1.6% suicide attempt rate involved two in combined treatment, two in fluoxetine treatment, one in CBT, and no suicides. As depression symptoms improved, suicidal ideation decreased. Combined CBT and fluoxetine had a more favorable safety profile than fluoxetine alone.

During the 36-week study, 44 participants (10.0%) had at least 1 suicidal event (23 episodes of suicidal ideation and 21 suicide attempts) (92). These occurred between 0.4 and 31.1 weeks with mean time of 12 weeks after study onset. Adolescents receiving fluoxetine alone had a significantly higher suicide event rate (14.7%) than those receiving CBT alone (6.3%). Combined treatment suicide event rate (8.4%) was not different from fluoxetine alone or CBT alone. Suicidal events were predicted by pretreatment severity of suicidal ideation and depressive symptoms.

Open 1-year community follow-up indicated gains at end of 36-week phase were maintained 1 year later (93). Need for improved long-term treatment of adolescent depression was suggested by 6% to 33% loss of benefit at follow-up, which represented substantial deterioration.

Treatment of Adolescent Suicide Attempters (TASA) study, developed by NIMH and five academic medical centers, was a combined psychosocial and pharmacologic

6-month clinical trial including 124 depressed adolescent suicide attempters to evaluate intervention and predictors and mediators of recurrent suicide attempts (94). It identified low 6-month risks for suicidal ideation and reattempts, suggesting this intervention be studied with controlled methodology.

Treatment of SSRI-Resistant Depression in Adolescents (TORDIA) study, sponsored by NIMH as a multicenter study, involved 12-week acute and 12-week continuation phases to evaluate treatment, after adolescents with MDD did not respond adequately to usual treatment with an SSRI drug (95–97). The 334 treatment-resistant adolescents with MDD and high risk for suicidal ideation or attempts or nonsuicidal self-injury included 70% females, 82% Whites, 60% with suicidal ideation, 50% with MDD for at least 2 years, and 52% with comorbid psychiatric disorders. At study baseline, 47% reported history of self-injurious behavior (23.9% nonsuicidal self-injury only, and 14% suicide attempts and nonsuicidal self-injury, and 9.5% suicide attempts only).

Participants had prior lack of response to SSRI before beginning TORDIA when prior SSRI treatment involved at least 8 weeks and in the last 4 weeks, SSRI dose was equivalent to 40 mg fluoxetine. In first 2 weeks of TORDIA, the failed SSRI was gradually decreased and discontinued while study medication was gradually added. Adolescents were randomized to one of four treatment groups including switch to a second SSRI (either citalopram, fluoxetine, or paroxetine at doses of 20 to 40 mg orally daily), switch to venlafaxine at doses of 150 to 225 mg orally daily, switch to a different SSRI plus CBT, or switch to venlafaxine plus CBT. TORDIA used weekly CBT, similar to that in TADS.

Acute phase results indicated greater decrease of depression with CBT plus switch to another medication (54.8%) than a medication switch alone (40.5%); but no difference in response between a second SSRI (47.0%) and venlafaxine (56.0%). No differences in response occurred for the four treatments regarding suicidal ideation or attempts or self-harm behavior. Suicide attempts occurred in 11.3% (18 suicide attempts among 17 participants and no suicide). Median time to suicidal event was 3 weeks after intake. New-onset suicide attempt rate was 5% and nonsuicidal self-injury was 9%. Venlafaxine was associated with more suicidal events and nonsuicidal self-injury for those with high baseline suicidal ideation. Strongest predictors of suicidal events were high baseline suicidal ideation, self-reported parent–child conflict, and drug and alcohol use. Those with suicidal events at study baseline continued to report high levels of depression and suicidal ideation, and were less likely to respond to treatment.

Adolescents with nonsuicidal self-injury plus suicide attempts had highest 24-week incidence of suicide attempts (7%), nonsuicidal self-injury (11%), and depressive symptoms, hopelessness, family conflict, and histories of physical and/or sexual abuse. Nonsuicidal self-injury history predicted suicide attempts as well as nonsuicidal self-injury and was a stronger predictor of future suicide attempts than

prior suicide attempts. Time to incident suicide attempts was predicted by baseline nonsuicidal self-injury and hopelessness. Time to nonsuicidal self-injury was predicted by history of nonsuicidal self-injury and physical and/or sexual abuse.

Depression Antidepressants and Psychotherapy Trial (ADAPT) was a 12-week acute and subsequent 16-week maintenance phase study conducted in England with 164 adolescents with MDD (98). Adolescents, assigned to SSRI medication plus CBT or SSRI medication alone, were assessed at baseline, and subsequent 6, 12, and 28 weeks. Results suggested no difference in outcomes of the two treatments; 20% did not respond. Predictors of suicide attempts were baseline serious suicidal ideation or acts, nonsuicidal self-injury, and poor family functioning. Predictors of nonsuicidal self-injury were baseline nonsuicidal self-injury, hopelessness, anxiety disorder, being younger and female. This study, like TORDIA, highlighted persistent suicidal and nonsuicidal self-injury in depressed adolescents.

Extensive discussion about safety of antidepressant drug treatment for children and adolescents began when United Kingdom Medicines and Healthcare Products Regulatory Agency (June 10, 2003) and U.S. Food and Drug Administration (FDA) (June 19, 2003) issued advisories recommending paroxetine not be prescribed to children and adolescents. FDA requested pharmaceutical companies submit their antidepressant clinical trials data about child and adolescent suicidal ideation and acts. Wyeth Pharmaceutical Company (August 2003) voluntarily changed labeling for pediatric use of venlafaxine and issued a letter to health providers indicating higher rates of suicidal ideation and acts and hostility in children and adolescents treated with venlafaxine in their clinical trials. After initial review of child and adolescent antidepressant treatment clinical trials, FDA issued an advisory (October 27, 2003) indicating association between antidepressants and suicidal ideation and acts. Additional FDA reviews resulted in a public advisory (March 22, 2004) indicating need for close observation of children, adolescents, and adults treated with antidepressants.

FDA conducted statistical analyses of randomized, double-blind, placebo-controlled pharmaceutical industry–sponsored child and adolescent studies of antidepressant drug treatment comparing incidence of suicidal ideation and acts for antidepressant drug treatment versus placebo (99). Manufacturers submitted to FDA data identifying suicidal ideation and acts, as adverse events in 22 industry-sponsored studies of various clinical indications involving 9 antidepressant drugs and a total of 2,298 children and adolescents treated with an antidepressant drug and 1,952 children and adolescents receiving placebo. Incidence of suicidal events was combined across clinical trials to yield risk estimates of suicidal ideation and attempts for those on antidepressant drugs compared to placebo. Risk estimate for serious suicidal adverse events was 1.89 (95% confidence interval: 1.18 to 3.04). FDA concluded treatment with antidepressant drugs was associated with suicidal events double the placebo rate.

FDA reanalysis on data from 23 clinical trials, involving 9 sponsored by pharmaceutical companies and the TADS study, evaluated whether antidepressant drugs used to treat 4,582 children and adolescents increased suicidal acts risk (100). Study drugs were bupropion, citalopram, fluoxetine, fluvoxamine, mirtazapine, nefazodone, paroxetine, sertraline, and venlafaxine. Psychiatric disorders included MDD (16 trials), OCD (4 trials), generalized anxiety disorder (2 trials), attention-deficit hyperactivity disorder (1 trial), and social anxiety disorder (1 trial). Four trials not reporting suicidal ideation or acts were dropped. Analysis from 20 studies focused on suicidal risk for each drug, for SSRIs in depression trials, and for all trials combined. TADS, using fluoxetine as antidepressant drug, was the only clinical trial with statistically significant risk ratio involving drug versus placebo (4.62, 95% confidence interval: 1.02 to 20.92). No child or adolescent in these studies committed suicide. Risk ratio for SSRIs in depression studies was 1.66 (95% confidence interval: 1.02 to 2.68) and for all drugs for all psychiatric indications was 1.95 (95% confidence interval: 1.28 to 2.98). Investigators concluded antidepressant drugs to treat children and adolescents were associated with increased suicidal ideation or acts risk. FDA mandated (October 15, 2004) pharmaceutical companies add a black box labeling for all antidepressants used for children and adolescents.

The FDA black box warning stimulated controversy about its validity and implications for clinical care of children and adolescents (101). Some suggested importance of the FDA black box warning was to remind prescribers and consumers of need for close monitoring for adverse behavioral effects during initiation or changes in antidepressant therapy (102). Others noted “rather than being a threat, the judicious clinical use of antidepressants actually does serve to effectively treat and indeed protect depressed patients from suicidal outcome” (103). Others believed that different outcome results may have been identified if other statistical analyses were used (104).

Study of large aggregate data indicated that national rates of diagnosing new-onset MDD in children and adolescents increased from 1999 to late 2003 but declined after the FDA advisory (October 27, 2003) through 2007 among primary care physicians, were unchanged among pediatricians, and increased among psychiatrists and rate of antidepressant prescription fills declined (105). A study of antidepressant prescribing for children and adolescents with depression, anxiety, or attention-deficit hyperactivity disorders indicated that compared to the period preceding the 2004 FDA boxed warning (2001 to 2003), a significant decline in antidepressant prescribing was detected in the immediate post-FDA boxed warning period (2006 to 2007) but increased in 2008 to 2009 (106). Another study, evaluating antidepressant dispensing and psychotropic drug poisonings as proxy for suicide attempts and suicides, reported decreased antidepressant use in 2005 among adolescents, young adults, and adults and significant increases in psychotropic drug poisonings for

adolescents, young adults but not adults (107). Associations between rates of antidepressant prescribing for children and adolescents and rates of suicide and nonfatal suicidal acts after 2009 have not been studied.

SUICIDE PREVENTION STRATEGIES

The increasing child and adolescent suicide rates in recent years suggest need for new suicide prevention strategies. Educating children and adolescents through school and family programs to cope with stress, develop effective emotional and behavioral self-regulation, and avoid substance use/abuse are important primary suicide prevention issues. Identifying early-life experiences that may interact with developmental vulnerability periods to increase suicidal risk need to be targets for primary prevention. New access prevention laws and educating parents about risks for guns or firearms at home are needed to restrict availability of guns and firearms (108,109). Enhancing accessibility to mental health care by reducing barriers for receiving help and improving collaborative care among health care providers are essential for reducing suicide risk.

Other suicide prevention efforts include development of valid universal screening and monitoring methods with excellent predictive capacity to identify combinations of proximal suicide risk factors. Effective real-time monitoring methods using mobile technology to identify transitions in suicidal states may enhance provision of immediate acute intervention. Recently, NIH announced sponsorship of a multisite study to identify biomarkers for suicide risk identification. Such studies may suggest strategies for precise treatment methods to reduce suicide risk. Greater understanding of sociocultural risk factors, such as use of social media, and development of primary prevention strategies to reduce youth risk are necessary. Public health education for the general public and health care professionals may reduce stigma and improve treatment-seeking for suicidal children and adolescents and when suicide occurs in families.

5.5 ANXIETY DISORDERS

CHAPTER 5.5.1 ■ ANXIETY DISORDERS

JEROME H. TAYLOR, ELI R. LEBOWITZ, AND WENDY K. SILVERMAN

INTRODUCTION

Anxiety disorders are the most common psychiatric disorders in childhood (1–3) and are associated with poor quality of life, depression (4), and significant societal costs (5). Pediatric anxiety is also associated with poorer obesity intervention outcomes (6). Anxiety is the emotional, cognitive, and physiologic reaction related to real or imagined threat that may occur in the future. Fear is the reaction that occurs when confronted with an actual threat, like seeing a snake or while flying. Anxiety and fear are emotions that can be adaptive. Adaptive anxiety, for instance, can foster appropriate preparedness for possible challenges in the future. Anxiety is viewed as a "clinical disorder" when the anxious reaction becomes so intense that it causes psychic distress or interferes with functioning (e.g., academic performance, family/peer relationships). Many childhood anxieties are developmentally appropriate, highlighting the importance in considering the child's age as well as sociocultural context. For instance, an increase in separation anxiety distress and stranger anxiety are developmentally appropriate around age 8 months, with symptoms usually resolved by age 2 years. Similarly, preschoolers are often afraid of the dark and monsters, and it is common for youngsters in elementary school to be afraid during storms. Developmentally appropriate worries fade with time and do not interfere with functioning, making them distinguishable from anxiety disorders.

The tripartite view of anxiety postulates that individuals' anxious responses consist of three components: behavioral or motoric, cognitive or subjective, and physiologic (7). The behavioral or motoric components involve avoidance of the situations in which the negative stimulus may be encountered. The cognitive or subjective components involve apprehension and distress about an event in the future and often relates to difficulties with control of situations. Cognitions often also involve worst-case scenarios that are unlikely to occur but viewed likely by the child. Physiologically, anxiety involves autonomic arousal that can include elevated heart rate, hyperventilation, sweating, flushing, and other somatic symptoms. The settings that evoke children's anxiety distinguish the specific anxiety disorders from one another, though these three response components are generally present across all anxiety disorders (8,9). In this chapter we use "children" for youths under 18 years old unless referring to a specific developmental period.

EPIDEMIOLOGY

In this chapter, we review separation anxiety disorder (SAD), selective mutism

(SM), specific phobia (SP), social anxiety disorder (also referred to as social phobia, SoP), panic disorder (PD), agoraphobia, and generalized anxiety disorder (GAD) in children and adolescents (Table 5.5.1.1). The age of onset of anxiety disorders is often determined by retrospective methods, and large prospective studies are lacking (10–12). The best estimates for prevalence in the United States are derived from the National Comorbidity Survey Replication Adolescent Supplement (NCSA) (3). The study surveyed a nationally representative cohort of 10,148 children 13 to 17 years old for DSM-IV diagnoses with structured in-person interviews. The prevalence and age of onset estimates were based on recall. Anxiety disorders were the most common mental health disorder with a 25% 12-month prevalence and 32% lifetime prevalence (posttraumatic stress disorder [PTSD] was included as an anxiety disorder and had a 4% 12-month prevalence and 5% lifetime prevalence with or without another comorbid anxiety disorder). Twelve-month and lifetime prevalence among adolescents for specific anxiety disorders were: SP—16%, 20%; SoP—8%, 9%; SAD—2%, 8%; agoraphobia—2%, 3%; PD—2%, 2%; and GAD—1%, 2% (3,13). SM was not included in NCSA, as this disorder was included as an anxiety disorder only in the 5th edition of the Diagnostic and Statistical Manual (14). In a study of 2,256 children in kindergarten to second grade, the point prevalence of SM was 0.7% (15,16). In NCSA, anxiety was less likely in adolescents whose parents were married or college graduates (2). In NCSA, girls were more likely than boys to have an anxiety disorder (2,3). However, study results have been mixed with regard to prevalence differences between boys and girls for pediatric anxiety disorders (10). For instance, a longitudinal study that followed children from latency to young adulthood found females were more likely than males to have an anxiety disorder in midadolescence and early adulthood but not overall (5).

The National Comorbidity Survey-Replication (NCSR) is the adult companion to the NCSA and the pediatric anxiety rates are based on retrospective reports. The median age of onset for anxiety disorders in the NCSR was 11 years (11). In NCSR, SoP, SP, and SAD began before adulthood in most cases; agoraphobia, PD, and GAD did not emerge in most cases until late adolescence or adulthood (11,13). In NCSR SAD was diagnosed based on DSM-IV criteria, which required onset of separation anxiety before age 18 years. DSM-5 removed the childhood-onset criterion for SAD, and thus NCSR likely underestimates the median age of onset for SAD. Silove et al. examined data from the World Mental Health Survey and found SAD onset can occur across the lifespan. The median age of SAD onset was in late adolescence in higher-income countries and in the mid-20s in lower-income countries (17). National studies on SM are lacking, though most studies suggest age of onset is usually before age 5 years (16).

In this section, we describe the DSM-5 anxiety disorders: SP, SAD, SoP, SM, PD, agoraphobia, and GAD (14). Illness anxiety disorder, which is based on the DSM-IV diagnosis hypochondriasis, was classified as a disorder related to somatic disorders in DSM-5 and is therefore not covered (14).

Specific Phobia

SP is an excessive fear of a specific object or situation. Exposure to the object or situation consistently results in immediate excessive and irrational fear that may manifest as hiding, clinging, freezing, crying, screaming, vasovagal fainting (especially in blood and needle phobias), or autonomic arousal. Symptoms must last for 6 months and cause significant avoidant behavior and/or distress, as well as functional impairment. Phobias are divided into five categories: animals, natural environment (e.g., lightning, heights, darkness), blood-injection-injury (including other medical procedures), situational (e.g., flying, driving, bridges), and other (e.g., loud noises, choking, clowns). Research indicates that only 17% of children with SP have a single phobia, and most children have multiple phobias (18). After traumatic and frightening experiences, SP or PTSD may develop; SP is only diagnosed when the criteria for PTSD are not met.

TABLE 5.5.1.1

KEY FEATURES OF ANXIETY DISORDERS

DSM-5 Anxiety Disorder	Key Points
Separation anxiety disorder (SAD)	Excessive worry about being separated from caregiver Duration: >4 wks in children, 6 mo in adults
Selective mutism (SM)	Lack of speech in particular situations (e.g., school) despite talking in other settings Duration: >4 wks, not limited to the first month of school
Specific phobia (SP)	Excessive fear of a particular object or situation Duration: >6 mo
Social anxiety disorder (social phobia, SoP)	Excessive fear of social situations or being observed. Fear of negative evaluation. "Performance-only" specifier if symptoms only occur around performances Duration: >6 mo
Panic disorder (PD)	Multiple panic attacks without identifiable trigger. Persistent apprehension about having a panic attack and/or excessive behavioral changes to avoid having panic attack Duration: >4 wks *Note:* Panic attacks can occur with any anxiety disorder. Panic attacks peak within minutes and often include physical sensations and discomfort, dissociative experiences, and fear of dying or losing one's mind. A medical work-up is often

	indicated
Agoraphobia	Avoidance of two of the following situations: public transportation, open spaces, enclosed spaces, crowds, and being outside of the home. The avoidance is due to unrealistic fears of being trapped or inability to get help if panic-like or embarrassing symptoms arise, or in children fear of getting lost. PD not required Duration: >6 mo
Generalized anxiety disorder (GAD)	Intense worry about multiple everyday tasks or situations. In children, only one additional symptom (e.g., poor sleep, fatigue, poor concentration, restlessness, muscle tension) is needed. Duration >6 mo with symptoms on most days

Separation Anxiety Disorder

SAD is developmentally inappropriate anxiety or distress relating to separation from a major attachment figure or caretaker. Children with SAD may worry about being kidnapped or lost and/or that separation may result in death or injury to their parents, and they will be unable to see their caretakers again. SAD frequently presents after parental loss, a significant illness in the family or child, death of a pet, or other stressful events (19). SAD may present with children's refusal to sleep alone or be away from home and nightmares about separation. It is not uncommon for SAD to be associated with somatic symptoms such as headaches, stomachaches, muscle cramps, or dizziness. If somatic symptoms occur only when children are separated from attachment figures or when faced with separation (e.g., no somatic symptoms on weekends when there is no school), anxiety is likely rather than other medical etiologies. Young children with SAD may report seeing shadows of monsters when left alone, and are more likely to cling to their parents, follow them from room to room, and/or insist parental presence at all times (e.g., bathing). SAD may result in school refusal and can prevent playing with friends outside of the home, going to sleep overs, or participating in overnight camps. Symptoms of separation anxiety must have a duration of at least 4 weeks in children, and 6 months duration in adults.

Social Phobia (SoP)

SoP is also known as Social Anxiety Disorder. It is an excessive and impairing fear of being negatively evaluated by others. SoP must be accompanied by either avoidance of social situations or severe discomfort while enduring social situations. In children, the anxiety cannot be limited to discomfort in social situations with adults. Children with SoP are unlikely to approach peers and often feel like others are watching them. Children with SoP may worry others will think they are weird, ugly, stupid, or clumsy. If forced to attend social gatherings, children with SoP may throw a tantrum prior to the event, and younger children may cry, freeze, or cling to adults in social settings. Eye contact is often uncomfortable for children with SoP,

posture may be overly rigid, and speech may be abnormally soft. Avoidance may involve retreating to one's room when company is present, eating lunch in a teacher's room instead of with other children, refusal to frequent public places such as malls or public restrooms (paruresis), and in severe cases almost complete self-isolation in the child's room, often accompanied by a reversal of diurnal cycles (20). Socially anxious children may worry about being judged by others who might notice physical symptoms of anxiety like blushing, sweating, or trembling voice. Most children and adolescents with SoP fear a variety of social situations, but when social anxiety is circumscribed to performing (e.g., sports, concerts, presentations), the diagnosis is "performance-only" SoP (14).

Before SoP is diagnosed, symptoms need to be present for 6 months and almost always occur in the feared social situation. Impairment helps distinguish between normative shyness and SoP. Examples of impairment include difficulties making or keeping friends, limited romantic relationships, school refusal, not participating in extracurricular activities, and significant child distress. Adolescents may abuse drugs prior to and/or during social situations in attempts to self-medicate. Family life also is often disrupted as the child's avoidance and impairment often constrains families' engagement in fun activities. The differential diagnosis includes avoidant personality disorder, which is sometimes conceptualized as a severe variant of SoP (21). Autism spectrum disorder is on the differential for SoP because social skills deficits from limited social interactions can mimic the social difficulties seen in autism spectrum disorder; however, children with SoP often have friends their own age and demonstrate improved social skills in established relationships. In many cases of autism spectrum disorder, a comorbid diagnosis of SoP is warranted.

Selective Mutism

SM is refusal to speak in particular settings. Children may speak at home but not school or in front of unfamiliar people. They may communicate by nodding, writing, or making sounds in lieu of speaking. Many children with SM rely on friends and parents to speak for them in social settings. Impairments due to SM include reduced class participation, academic underachievement, and isolation from peers. Symptoms must persist for 1 month and cannot be limited to the first month of school. The failure to speak cannot be due to a physical inability to speak. Children with SM are often shy and usually have comorbid social phobia (16); however, some enjoy participating in social activities that do not require speaking. Communication and developmental disorders are frequently comorbid with SM (22), and children with SM, communication, and developmental disorders all present with a lack of speech. What distinguishes children with SM from children with communication and developmental disorders is that the former have an ability to speak in certain social contexts but not in others (22).

Panic Disorder

PD is defined by having panic attacks, at least some of which *do not* have identifiable precipitants. A panic attack is a set of distressing symptoms that classically peak within 10 to 15 minutes. Physical symptoms include trembling, dizziness, palpitations, difficulties breathing, nausea, and vomiting. Derealization (i.e., out-of-body experiences) and fear of dying and/or losing one's mind may also occur. Ruling out medical etiologies is required before diagnosing panic attacks. Medical causes for panic-like symptoms include cardiac arrhythmias, hyperthyroidism, hyperparathyroidism, seizures, vestibular disorders, asthma, and neuroendocrine tumors like pheochromocytoma. In collaboration with the pediatrician, a medical evaluation including physical examination, laboratory tests, and an EKG (especially in the case of cardiac symptoms) should be considered. Cardiology consultation should also be considered. Once medical causes are ruled out, it is important to determine whether the panic attacks are evoked by stimuli associated with other disorders (e.g., panic in social evaluative settings may suggest a diagnosis of Social Anxiety with Panic Attacks). When panic attacks occur solely in response to particular situations, PD is not diagnosed. Children with PD have panic attacks without an identifiable cause and may have additional panic attacks that are associated with exposure to specific situations. Nocturnal panic attacks, which awaken an individual from sleep, are usually pathognomonic for PD.

Key to PD diagnosis is the presence of worry about having a panic attack or behavioral changes in attempts to avoid an attack or reduce possible harm due to an attack. Children with PD may not take stairs or participate in sports because of beliefs that increased heart rate might trigger a panic attack. They may only go outside with others who could help if an attack occurs. The worry or behavioral changes must be present for at least 1 month. Increased anxiety sensitivity, or the fear of anxiety-related sensations (e.g., increased heart rate, dizziness, or derealization) due to beliefs that these sensations have harmful physical, psychological, or social consequences is particularly common in PD, though anxiety sensitivity is experienced by children with other anxiety disorders as well (23,24). Somatic symptom disorder is similar to PD in that troubling somatic symptoms are often prominent. However, in PD, somatic symptoms usually present in relatively brief and intense episodes in contrast to the persistently present symptoms of somatic symptom disorder (14).

Agoraphobia

Agoraphobia is a fear of being unable to escape or get help in the event of overwhelming or embarrassing symptoms (e.g., panic symptoms). Avoidance must occur in at least two types of setting categories. The five categories of avoided situations are (1) public transportation, (2) open spaces (e.g., bridges, parking lots),

(3) enclosed spaces (e.g., stores, basements, elevators), (4) crowded areas, and (5) anywhere outside of the home alone. In agoraphobic children a prominent fear is getting lost. Symptoms often begin following parental loss, life-threatening situations, or other scary situations that may produce feelings of helplessness. Agoraphobia can occur with or without PD (e.g., if fear of fainting leads to the avoidance, PD is not diagnosed). Symptoms usually last at least 6 months before a diagnosis is made. As in agoraphobia, children with SAD may fear getting lost and/or leaving home. In SAD, however, the fear relates to separation from the caretaker and not seeing the caretaker again. In agoraphobia the fear is about encountering a dire situation in which help is needed but unavailable. Further, unlike the commonly early onset for SAD, agoraphobia does not typically have an onset until late adolescence and early adulthood.

Generalized Anxiety Disorder

GAD is characterized by impairing worry about multiple situations for at least 6 months. Children with GAD express worry about potentially negative occurrences on most days, and the focus of the worry may shift from topic to topic. The anxiety in GAD is often difficult to control and interferes with completing tasks or enjoying activities, which helps to distinguish pathologic from normal anxiety. Children with GAD may have difficulties falling or staying asleep, fatigue, trouble focusing, muscle tension, or irritability, and worry must be accompanied by one of these symptoms in childhood GAD (note, diagnosis of GAD in adults requires worry be accompanied by three of these symptoms). Anxieties in GAD often involve everyday matters like completing assignments, being on time, getting good grades, and performance in sports. Worry about anticipated changes and dangerous situations like storms, home invasion, or a family member getting sick is also common. The worries can sometimes be fantastical (e.g., monsters in the basement) or extreme (e.g., terrorist attacks). Children with GAD may seek reassurance about their performance or safety frequently. GAD may also present as perfectionism, indecision for fear of making a poor choice, and a tendency to magnify minor mistakes. Somatic symptoms also often manifest including headaches and stomachaches. There is significant overlap between depressive and GAD symptoms, including sleep changes, low energy, difficulties concentrating, psychomotor changes, and irritability (particularly common in adolescent depression). In addition to symptom overlap, there is significant overlap in the age prevalence curves of GAD and depression (5): they both are relatively uncommon in younger children and increase throughout adolescence and young adulthood.

COMORBIDITY

The various anxiety disorders have many overlapping symptoms and somatic manifestations. Anxiety disorders are highly comorbid with each other and other disorders. GAD is the anxiety disorder most likely to be comorbid with another anxiety or mood disorders. In NCSA, children with GAD had a 66% lifetime comorbidity rate with other anxiety disorders: 41% with SP; 21% with SAD; and 20% with SoP (25). Children with GAD had a 59% lifetime comorbidity rate with mood disorders (e.g., major depression, dysthymia, and bipolar). In the large prospective Great Smoky Mountain Study (GSMS), described in detail in the "course of illness" section below, GAD increased the odds of having every other anxiety disorder, except agoraphobia (but there was a trend that linked GAD and agoraphobia, $p = 0.06$) (5). Still, GAD was more closely associated with depression than any other individual anxiety disorder. The converse was also true—depression had a stronger association with GAD than the other individual anxiety disorders. GAD also increased the odds of having a behavioral disorder, which included conduct disorder, oppositional defiant disorder (ODD), attention-deficit hyperactivity disorder (ADHD), and substance disorders.

SoP was associated with drug-use disorders but not alcohol-use disorders in NCSA (26). In GSMS, SoP was most tightly associated with SP with over one-half of patients with SoP meeting criteria for SP during the course of the study (5). SoP was also associated with GAD, depression, and agoraphobia. For SP, the more types of SPs that adolescents in NCSA had, the more likely they were to have mood disorders and ADHD (18). The blood-injection-injury SP subtype was specifically associated with ADHD and children with situational-type SPs (e.g., flying, bridges) were more likely to be diagnosed with conduct disorder. Adolescents with anxiety disorders in NCSA had higher lifetime prevalence of intermittent explosive disorder (23%) compared to adolescents without a history of anxiety (8% intermittent explosive disorder prevalence), and the association was particularly robust between intermittent explosive disorder and SoP and PD (27). Interestingly, although PD and agoraphobia commonly co-occur, PD was more strongly associated with GAD, depression, and SAD in childhood through young adulthood in GSMS relative to agoraphobia (5). SoP and developmental disorders are frequently comorbid with SM (16,28). In a sample of children 3 to 17 years old with SM, 68% had SoP, 43% had a phonologic disorder, 32% had an elimination disorder, 17% had a developmental coordination disorder, and 17% had mixed expressive–receptive language disorder (22).

COURSE OF ILLNESS

A tendency toward negative affectivity (i.e., experiencing fear, shame, anger, sadness, and low self-esteem) is widely observed in children before they develop anxiety disorders (29). Many children with SoP displayed patterns of behavioral

inhibition (avoidance of novel experiences) in the first few years of life (30). Once childhood anxiety disorders develop, they tend to be chronic (3,31). SAD is the anxiety disorder least likely to be chronic (17). In NCSA 79% of teenagers who were previously diagnosed with SAD no longer met criteria during the previous 12 months, and in NCSR 64% of childhood SAD cases resolved by adulthood (3,32). SAD with comorbid ODD and severe ADHD is more likely to persist into adulthood (33). Rates of partial or full remission in NCSA for the previous year were 9% in SoP, 18% in SP, 18% in PD, 25% in agoraphobia, 49% in GAD, and 79% in SAD (partial or full remission defined as no longer meeting full diagnostic criteria during the past year) (2,3). Children whose social phobia persists into adulthood are less likely to achieve full occupational potential and have fulfilling social relationships (34). Studies with small samples have found most but not all children with SM improve by young adulthood, with more severe cases having poorer outcomes (35). Larger longitudinal studies of SM are needed.

Prospective longitudinal studies are best suited to track the course of illness. The Great Smokey Mountain Study (GSMS) was a prospective longitudinal study designed to examine the course of mental illness from childhood to early adulthood (36). The study began in the 1992 and has followed the cohort for nearly 25 years (37). GSMS had 1,420 participants from predominantly rural communities in North Carolina, United States. Participants were 9 to 13 years old at enrollment. Copeland et al. (2014) examined the course of anxiety from age 9 years to 26 years (36). GSMS found childhood anxiety disorders were associated with poorer outcomes in young adulthood. Specifically, childhood SAD was associated with poorer self-reported medical health (e.g., smoking, obesity, chronic illnesses) in young adulthood. Childhood SoP was associated with poorer self-reported interpersonal outcomes (quality of relationship with friends and loved ones) in young adulthood. Childhood GAD was associated with poorer self-reported health and financial outcomes (poverty, debt level) as a young adult (5). Moreover, children with GAD are at increased risk for developing depression, and the temporal association is bidirectional—that is, having GAD as a child increases the risk for adulthood depression and having major depression as a child increases the risk for adult-onset GAD (38).

A study examining GSMS data of children aged 9 to 16 years found a trend toward an association between anxiety and subsequent suicidality (defined as intrusive thoughts of wanting to die, kill oneself, or a suicide attempt) (odds ratio = 2.5, $p = 0.07$ after adjusting for comorbid disorders and demographic characteristics) (39). The analysis found a significant association between depression and subsequent suicidality (adjusted odds ratio = 21.7, $p < 0.05$). Risk for suicidality was greatest for those with comorbid depression and GAD (39).

ETIOLOGY

Learning is viewed as key in the etiology and maintenance of phobias and anxiety disorders (40). Rachman theorized three pathways (41). First, children may learn to fear stimuli verbally—that is, from others saying certain stimuli are dangerous. Second, children may learn vicariously by observing others experience distress when confronted with certain stimuli. Third, children may learn to avoid certain stimuli based on their own direct traumatic experiences. There are two types of learning processes involved in etiology and maintenance: classical conditioning and operant conditioning. Classical conditioning, also known as Pavlovian conditioning, occurs when a neutral stimulus is paired with an aversive stimulus (e.g., an electric shock) repeatedly such that the neutral stimulus becomes associated with distress. The automatic and associative learning in classical conditioning is thought to play a role in the development of phobias and anxiety disorders (e.g., a child develops a water phobia after a near-drowning experience) (42). The other learning process is operant conditioning, which occurs when an individual makes a choice based on desired outcomes (reinforcements) and/or displeasing consequences (punishments) that have resulted from the choice previously. For instance, after a child is humiliated in front of a peer group, operant conditioning may motivate the child to voluntarily avoid social interactions. Volitional avoidance of threatening stimuli contributes to the disability associated with anxiety disorders. While learning may contribute to the development of anxiety disorders, other mechanisms are also implicated.

Risk factors for developing anxiety disorders include physical or sexual abuse, parental loss, early-life stressors, parental overprotectiveness, and overcontrolling parental behaviors (43,44). A meta-analysis that included data on 8,907 children found insecure attachment, particularly ambivalent attachment, was associated with anxiety disorder development (45). Early-life stressors can affect brain development (46). Gee et al. used functional magnetic resonance imaging to examine the amygdala–medial prefrontal cortex connectivity of 41 healthy children 6 to 17 years old who had been institutionalized in orphanages in various other countries for an average of 22 months before age 8 and compared these previously institutionalized scans to the scans of 48 never-institutionalized youths. At the time of the study, the previously institutionalized children were living with high-income adoptive families in the United States. The study found that children with a history of being institutionalized had more mature amygdala–medial prefrontal cortex connectivity relative to children without histories of institutionalization (47). The changes were mediated by cortisol, intimating the changes in connectivity were related to stress and hypothalamic–pituitary–adrenal axis activity. The connections between the prefrontal cortex and amygdala are often described as the "fear circuit" (48–50), and it is possible that the impact of early-life stress on this circuit partially explains the link between early childhood adversity and anxiety disorders. In addition to the amygdala and prefrontal cortex, the hippocampus and cingulate gyrus are thought to be involved

in the neurocircuitry of anxiety (48,51,52).

Anxiety disorders are caused by both genetic and environmental factors. Heritability is the proportion of the illness likely due to genetics and ranges from 0% to 100%. Estimates of anxiety disorder heritability have ranged from 20% to 50% in twin studies (53–55). Several studies have investigated the role of the serotonin transporter gene promoter (5-HTTLPR) in anxiety, though the findings are equivocal. However, a meta-analysis in 2013 found that the short allele of 5-HTTLPR had a small but statistically significant effect on amygdala reactivity (56). Similarly, a 2013 meta-analysis found the 5-HTTLPR genotype was associated with cortisol stress reactivity (57). Amygdala response to potential threats and cortisol stress reactivity have been implicated in anxiety disorder etiology (47,48). Further research is needed to clarify whether 5-HTTLPR plays a role in anxiety.

Anxiety disorders run in families, and children of anxious parents are more likely to exhibit clinical levels of anxiety than children of nonanxious parents, a consistent finding that has been confirmed in large-scale population studies (58,59). Although this is explained in part by shared genetics, nongenetic factors also contribute to the heritability of anxiety disorders. Anxious caregivers may promote more avoidance in the child by providing higher levels of family accommodation, or changes to their own behavior aimed at helping the child avoid or alleviate distress related to the anxiety (60,61). More anxious parents may also directly model fearful and avoidant behavior, providing the child with more opportunities for vicarious fear learning and with less modeling of nonavoidant coping skills (62).

While anxiety disorders share many risk factors, presumably there are etiologic distinctions underlying each disorder. For instance, one hypothesis posits that PD may be due to high anxiety sensitivity or oversensitivity to physiologic arousal (23,24). The cycle of recognizing benign physical variance in breathing and heart rate results in worry, which in turn increases physical arousal, self-perpetuating the spiral toward a panic attack. Evidence also points toward an oversensitivity to carbon dioxide (CO_2) as a cause for PD (i.e., suffocation model) (63). Both SAD and PD patients are likely to experience panic-like symptoms when exposed to CO_2-enriched air (64). Of note, SAD is a risk factor for subsequently developing PD (65,66). Studies have found genetic factors common to SAD and PD likely influence sensitivity to CO_2 (19,48). Also, it is theorized that many SPs have an evolutionary basis because exaggerated fears of dangerous animals or natural environments may have conferred a survival advantage earlier in human history (67). In addition to genetic predisposition, many phobias have an identifiable traumatic or frightening experience that resulted in the development of SP. Recent research has implicated the oxytocinergic system in childhood anxiety disorders, in particular in the anxious children's reliance on parents for proximity and family accommodation. Children with SAD were found to have lower levels of peripheral oxytocin compared to anxious children with other anxiety disorders, and the oxytocin levels were

significantly linked to the degree of family accommodation reported by the mothers (68). Furthermore, a follow-up study found that the differences in oxytocin levels were no longer apparent after the children were allowed to interact with their mothers for a few minutes (69).

ASSESSMENT

The gold standard for assessing childhood anxiety in research studies is the Anxiety Disorders Interview Schedule—Child and Parents (70). Whether in research or clinical settings, a multisource, multimethod assessment approach is useful for accurate and valid assessment of childhood anxiety. There is moderate agreement on anxiety levels between parent and child reports of anxiety, and child–parent agreement is usually higher for children older than 12 years (71). Becker et al. (72) found child–parent agreement was higher on overt behavioral symptoms of SAD and school refusal compared with the less overt symptoms in SoP and GAD. Clinical assessment tools include rating scales for anxiety disorder screening, diagnosis, and monitoring treatment effects, and most include parent and child versions (see Byrne et al., 2017 for review) (73,74). The Screen for Child Anxiety Related Disorders (SCARED) is a scale commonly used to screen for anxiety with child self-rating and parent-rating versions (75). The Multidimensional Anxiety Scale for Children 2 (MASC2) is another commonly used scale with child self-rating and parent-rating versions (76). The Pediatric Anxiety Rating Scale (PARS) has questions for the child and parent, and the final score is based on clinician ratings of frequency, severity, and impairment due to symptoms (77). The Family Accommodation Scale—Anxiety (FASA) (60,78) is the most widely used scale for assessing family accommodation, or the degree to which parents change their own behavior to help their child avoid feeling anxious. There are both parent and child report versions of FASA and the total accommodation score is based on the ratings of frequency of various forms of accommodation (e.g., providing reassurance to the child).

In children presenting with anxiety, it is important to rule out substance/medication-induced anxiety. Medications that can cause anxiety include albuterol, oral steroids, pseudoephedrine, stimulants, and bupropion. Importantly, although stimulants may provoke anxiety, a 2015 meta-analysis found that in children with ADHD, stimulant treatment had a lower risk of anxiety as a side effect compared to placebo (79). Many antidepressants including selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) can cause anxiety, particularly at initiation. Fenfluramine/phentermine and other diet supplements are often anxiogens. Withdrawal from short-acting benzodiazepines can also present with anxiety symptoms. A wide array of illicit substances including marijuana, cocaine, anabolic steroids (e.g., testosterone), hallucinogens, and phencyclidine can result in anxiety. Use and withdrawal from

nicotine and caffeine can produce anxiety. Environmental etiologies of anxiety include exposure to organophosphates and ingestion of lead in paint chips, arsenic in soil, and other toxic metals.

TREATMENT

A primary goal of treatment is for children to learn how to manage and cope with their excessive and impairing anxiety. Given the high comorbidity of the anxiety disorders, it is common to target the most impairing anxiety disorder first. In this way, success can be attained and the child comes to understand that the anxiety is manageable, and that the skills learned can be applied to the comorbid problems. Treatment of anxiety disorders affecting sleep should also be prioritized (80). First-line interventions for childhood anxiety disorders are cognitive behavioral therapy (CBT) (81) and treatment with SSRI (82–84).

PSYCHOTHERAPY

CBT is a first-line treatment for pediatric anxiety (85–87). CBT for anxiety usually includes psychoeducation about anxiety, self-monitoring of emotions and somatic manifestations of anxiety, relaxation techniques (e.g., deep breathing and progressive muscle relaxation), tracking behavioral patterns contributing to anxiety, graded exposure to feared stimuli, identification of thoughts (e.g., negative self-talk) that influence feelings, cognitive restructuring, problem-solving skills, reward systems, and relapse prevention. Practicing skills between sessions is a key element of CBT. Parents receive psychoeducation and help execute the behavioral reward system (88). CBT is usually comprised of 50- to 60-minute individual sessions every week for 12 to 20 weeks. Variations on CBT include Panic Control Treatment for Adolescents (PCTA), which includes traditional CBT elements and adds exposure to feared bodily sensations like hyperventilation or tachycardia (i.e., interoceptive exposure) in order to treat PD (89). For SP, a randomized controlled trial (RCT) found that one 3-hour CBT session was efficacious (90). Group CBT with concurrent child groups and parent groups are also effective in treating childhood anxiety (91), and have outcomes similar to individual CBT (92). It is possible that an exception is for children with SoP, who may benefit more from individual CBT relative to group CBT, but more research is needed (93). Web-based CBT with minimal therapist support is also efficacious (94).

Silk et al. found CBT was more effective than supportive therapy in pediatric anxiety. In an RCT comparing individual CBT with child-centered supportive therapy, remission rates (i.e., no longer meeting diagnostic criteria for SoP, GAD, or SAD) were higher for children randomized to CBT (67%) relative to supportive

therapy (47%), and CBT superiority was maintained at 1-year follow-up (95). However, another study found that CBT and usual care in an urban mental health clinic had similar primary anxiety disorder remission rates—58% in usual care and 50% in CBT (96). Less robust findings in effectiveness trials (as opposed to efficacy trials) highlight the need for more community studies beyond the more carefully protocolized RCTs (92). Recent work has begun to pool the findings of studies that have been conducted (86,87). A 2012 meta-analysis found that among psychotherapeutic interventions for anxious youth, CBT has the most evidence with a small to medium effect size relative to active treatment controls (97).

Social effectiveness training is an evidence-based treatment for SoP that combines social skills training and behavioral therapy. A 12-week RCT of children with SoP found social effectiveness training was more effective than fluoxetine (98). In social effectiveness training, children had two sessions per week—one group session and one individual session. Social skills training was conducted in group format and included lessons on initiating and maintaining conversation, joining groups of peers, and nonverbal skills like eye contact. Immediately after social skills training, the group practiced the social skills during social outings (e.g., bowling, visiting museums, or going out to eat) aimed at "peer generalization" of the skills. Individual sessions included exposures based on the unique social fears of the child. After 12 weeks, remission rates were 53% with social effectiveness training, 21% with fluoxetine, and 3% with placebo. The treatment gains from social effectiveness training are especially notable because children with SoP generally have poorer treatment outcomes compared to children with other anxiety disorders (99,100). Furthermore, a prior study found that children with SoP who received only CBT had poorer outcomes than children who received SSRI (101).

Bergman et al. conducted an RCT in which 21 children (age 4 to 8 years) with SM were randomized to a waitlist control group or a 24-week behavioral intervention. The behavioral intervention included graded exposure to speech, a reward system, parent and teacher involvement, and some cognitive restructuring when developmentally appropriate. The intervention had a 75% treatment response rate, while the waitlisted group did not significantly improve (101). An RCT by Oerbeck et al. with 24 children (3 to 9 years old) with SM found a 3-month intervention with a behavioral reward system, an in-home component, and an in-school component involving teachers and peers was efficacious, while children on the waitlist did not improve (102). Younger children with SM had better outcomes in both studies. A pilot study by Ooi et al. randomized 21 Singaporean children (age 6 to 12 years) to a therapist-guided web-based CBT program for 14 weeks or the control group in which children played computer games while interacting with the therapist. Children in both groups improved and there were no between-group differences (103). Unlike prior studies, the web-based CBT was compared to an active control instead of a waitlist control. Furthermore, unlike other randomized trials with behavioral

intervention components, in this web-based intervention the parent and teacher components were supplementary and not included in the pilot study. In summary, there is evidence for behavior interventions in children with SM when parents and teachers are active participants in the treatment program. Effective behavioral interventions for SM included psychoeducation, behavioral reward systems, and graded exposure. SM treatment should focus on social and academic functioning. Finally, once the child begins to speak, overzealous celebration can result in regression.

Limited evidence supports the use of psychodynamic psychotherapy for pediatric anxiety. In psychodynamic terms, anxiety can be viewed in the context of unacceptable desires and defense mechanisms used to respond to the desires. Failings of defense mechanisms can cause anxiety that interferes with function (104). Gottken et al. (2014) used short-term manualized psychoanalytic child therapy (PaCT) in weekly sessions for 6 months in 30 children (4 to 10 years old) with any DSM-IV anxiety disorder (the most common anxiety disorders were SP and GAD). PaCT included 5 to 6 parent sessions, which focused on improving the parent–child relationship, mentalizing capacity, and parental reflective functioning. Three children (10%) dropped out. Eighteen children (60%) achieved remission with PaCT and no children achieved remission on the waitlist. Remission was defined as no longer meeting criteria for any anxiety disorder (105).

Children with histories of autism spectrum disorder, bipolar, and psychosis have been excluded from many large RCT examining interventions in pediatric anxiety (85,106). However, multiple studies have demonstrated that CBT is effective in reducing anxiety in children with autism spectrum disorder and comorbid anxiety (107–111). Studies examining effective treatments for anxiety in children with histories of bipolar disorders and psychotic disorders are needed.

PHARMACOLOGIC

SSRIs are effective treatments in pediatric anxiety (83,85,106,112). Serotonin and norepinephrine reuptake inhibitors (SNRIs) are also effective in pediatric anxiety; however, there is substantially more evidence supporting the efficacy and tolerability of SSRI. A 2015 meta-analysis of RCTs investigating the efficacy of SSRIs and SNRIs found a medium effect size (Cohen's $d = 0.62$) relative to placebo in SAD, SoP, and GAD. Medications with more serotonergic specificity had a greater effect size in post hoc analyses—sertraline and fluvoxamine had effect sizes >1.4 and paroxetine, fluoxetine, venlafaxine, and duloxetine had effect sizes <0.7 (84). The meta-analysis did not find evidence of increased risk for suicidality with antidepressants; however, there was a strong trend toward activation (odds ratio = 1.86, $p = 0.054$).

There are few pharmacologic RCTs conducted on SM, and most are limited by

very small samples. One of the largest pharmacologic trials was conducted by Black and Uhde in which 15 children 6 to 12 years old with SM were randomized to double-blind treatment with either fluoxetine or placebo for 12 weeks. There were no significant differences in clinician- and teacher-ratings between the two groups at the end of the study, though parents rated significant improvements in SM symptoms in children who were randomized to fluoxetine. Most children in both groups continued to have considerable impairment due to SM (113). Fluoxetine was well tolerated, and there was no significant difference in side effects between the fluoxetine and placebo group. In short, SSRIs may reduce symptoms in SM, though more research is needed (114).

There is a dearth of evidence for other medications in childhood anxiety. An 8-week small open-label study investigating the efficacy of mirtazapine in 18 children 8 to 17 years old with SoP had a 56% response rate, and 22% discontinued due to adverse effects; mirtazapine also caused significant weight gain (3.3 kg) (115). Geller et al. found atomoxetine, which selectively inhibits norepinephrine reuptake, improved anxiety and ADHD symptoms in children with both disorders (116). RCTs examining the efficacy of benzodiazepines in pediatric anxiety have been negative, but the studies may have been underpowered (117,118). An unpublished Bristol-Meyers Squibb 2010 RCT with 559 children found buspirone (15 to 60 mg/day in divided doses) for 6 weeks was not significantly more effective than placebo in reducing pediatric anxiety (83). Evidence for the use of tricyclic acids is lacking. Given the substantial evidence for SSRIs relative to other agents, multiple SSRIs should be tried prior to trials of other psychotropic agents in pediatric anxiety.

CHILD/ADOLESCENT ANXIETY MULTIMODAL STUDY

The Child/Adolescent Anxiety Multimodal Study (CAMS) is the largest RCT investigating treatments for anxious youth. CAMS randomized 488 children aged 7 to 17 years who met DSM-IV criteria for GAD, SoP, or SAD to 12 weeks of treatment with sertraline (SSRI), CBT, combined sertraline and CBT, or pill placebo (85,119,120). Combined treatment was most efficacious, there were no significant differences between sertraline and CBT, and placebo had the poorest outcomes. Remission rates, or no longer meeting diagnostic criteria at week 12, were 68% with combined treatment, 46% with sertraline, 46% with CBT, and 24% with placebo (100). Response rates (i.e., “much improved” or “very much improved” on the Clinician Global Impression-Improvement scale) at week 12 were 81% for children in combined treatment, 61% for CBT, 55% for sertraline, and 24% in placebo (85). In severe anxiety, combined treatment is usually needed to achieve symptom remission (121,122). In milder anxiety, given the high response rates to monotherapy with CBT, CBT should be considered before medications.

A predictor and moderator analysis of the CAMS study by Compton et al. found

patients with SoP had superior outcomes when sertraline was included in the treatment regimen and that patients with GAD had greater reductions in anxiety if CBT was included in the regimen (100). Superior outcomes with medication in SoP may be due to youth who may be too socially anxious to fully engage in psychotherapy. Children with SAD particularly benefitted from combined treatment relative to children with other anxiety disorders. Older age, minority status (i.e., either non-White race or Hispanic ethnicity), more severe baseline anxiety, having comorbid depression or additional anxiety disorders, and the presence of SoP were associated with a lower likelihood of symptom remission (99).

There was no significant difference in spontaneously reported physical or psychiatric side effects in youth who received sertraline (dosed 25 to 200 mg) or placebo in CAMS (123). Children aged 12 years and younger reported more adverse events than older children with sertraline (4% in adolescents vs. 16% in children 12 years old and under). Children who received sertraline were most likely to report increased trouble with sleeping on the Physical Symptom Checklist (28% in sertraline, 16% CBT, 15% combined, 13% placebo). There were no suicide attempts in any treatment condition in CAMS.

The acute responders, or those whose symptoms improved at week 12, in CAMS were followed for 6 additional months (119). Children who received CBT were given monthly booster sessions and children prescribed sertraline received monthly medication appointments. Children were allowed to have additional treatment from providers outside of the study during the 6 months of follow-up. At 6 months, combined treatment demonstrated slight superiority over monotherapy, and CBT and sertraline continued to have similar outcomes at 6 months (119). In a naturalistic study, 288 of the children in CAMS were followed for a mean of 6 years in Child/Adolescent Anxiety Multimodal Extended Long-term Study (CAMELS) (124). Nearly half (47%) of the children in CAMELS were in remission. A greater percentage of acute responders were in remission than nonresponders (52% remission in acute responders and 38% in acute nonresponders). Male sex and better baseline family functioning were predictors of remission at 6 years.

OTHER INTERVENTIONS

CAMS provided support for the use of CBT and SSRIs as first-line treatments in childhood anxiety. However, many children do not respond to first-line treatments. Attention bias modification, which aims to reduce anxious children's unconscious predilection to pay over-attention to threatening stimuli has demonstrated success in RCTs (125–127). Parent-based programs aimed at reducing family accommodation by parents such as Supportive Parenting for Anxious Childhood Emotions (SPACE) are also showing promise (128).

CONCLUSION

In summary, pediatric anxiety disorders are common, and diagnosis requires functional impairment or substantial distress. Further evidence is needed to determine the precise etiology of anxiety disorders; however, the evidence suggests that both genetic and environmental factors play a role in the development of anxiety disorders. During the last decade, several studies have confirmed the efficacy of SSRIs and CBT. Future research is needed to identify effective interventions for children whose anxiety does not remit with SSRIs or CBT. Finally, future studies should examine how psychiatric comorbidities like bipolar spectrum disorders affect treatment efficacy.

CHAPTER 5.5.2 ■ OBSESSIVE-COMPULSIVE DISORDER

KENNETH E. TOWBIN AND MARK A. RIDDLE

INTRODUCTION

Detailed descriptions of obsessions and compulsions are found among the oldest records of mental illness known. Classic obsessions and compulsions, depicted as possession by the devil, date back in 1467 in *Malleus Maleficarum* (1) and are described in the "Obsessi" of Paracelsus in the 16th century. In the 1600s, pious texts tell of extremes of religious doubting and "scrupulosity," or excessive devotion (2). Pioneers of psychiatry such as Esquirol (3), Maudsley (4), Freud (5), and Janet (6) took up these intriguing symptoms, and their writings reflect the prevailing views on the nature of thought, motivation, and free will.

DEFINITIONS

Obsessions are unwanted thoughts, images, or impulses that are recognized as senseless or unnecessary, intrude into consciousness involuntarily, and cause functional impairment and distress. Despite this lack of control, a person with obsessions is aware that these thoughts originate in his or her own mental activity. Since they arise in the mind, obsessions can take the form of any mental event—simple repetitive words, thoughts, fears, memories, pictures, or elaborate dramatic scenes.

Compulsions are repetitive actions that are responses to obsessions or perceived internal obligations to follow certain rituals or rules. They are distressing and cause functional impairment. Compulsions may follow directly from obsessions or indirectly as efforts to ward off certain thoughts, impulses, or fears. Children often report that their compulsions do not have a preceding mental component. Like obsessions, compulsions are often viewed as being unnecessary, excessive, senseless, involuntary, or forced. Individuals suffering from compulsions will often elaborate a variety of precise rules for the chronology, rate, order, duration, and number of repetitions of their acts.

These definitions reflect three critical concepts that are relevant to the differential diagnosis—unwanted/distressing, senseless/excessive, and impairing. An essential criterion is that symptoms produce functional impairment. The other two follow classic definitions (4,7). While most patients view their compulsions as unnecessary and their obsessions as senseless, for some, such awareness ("insight") may be absent or intermittent (8). Although the capacity for insight falls along a continuum

(9), DSM-5 offers three categories (absent, poor, fair/good) (10). Patients with insight see their actions as senseless or excessive, those with poor insight think their actions are "probably necessary" (10), and those without insight are nearly delusional, entirely convinced that their actions are necessary.

Few studies differentiate between participants with childhood- and adolescent-onset obsessive-compulsive disorder (OCD). Therefore, in this chapter, "child," "childhood," or "children" will be used to signify children *and adolescents*. When studies are drawn solely on adolescent participants, the more restrictive term will be employed.

PREVALENCE AND EPIDEMIOLOGY

The prevalence of OCD in childhood should be understood in the context of the high prevalence of *subclinical* obsessions or compulsions and of developmentally appropriate magical thinking in children. In children less than 6, urges to make things "just right" and preoccupations with symmetry and rules are very common and typically decline after age 6 (11). A majority of fourth graders experience preoccupations with guilt about lying and engaging in checking behaviors and 50% report contamination and germ fears (12). By eighth grade, rates for these concerns declined to 40%, but 60% of eighth graders reported worries about cleanliness and 50% noted intrusive rude thoughts (12). However, even in this older population, rates of these behaviors and thoughts declined over time. Prevalence and incidence rates are heavily influenced by which diagnostic criteria are applied (13–16) and how diagnoses are made (such as using structured interviews by nonclinician interviewers or computers) (14–17).

Given the methodologic shortcomings of most epidemiologic studies, there is no consensus on the lifetime prevalence and incidence of OCD. Overall, the lifetime prevalence of OCD is probably greater than that reported in the 1950s (0.05%), but less than 1.3% to 3.3% reported in the ECA (18). At this point the best one can say is that, the lifetime prevalence in adults is probably between 0.5% and 2% (13,14,19–21).

Methodologically more reliable studies suggest that OCD shows an equal sex distribution. Compared to females, males with OCD appear to have an earlier age of onset (20,22–24), and a longer duration of illness prior to seeking treatment (24). Delays in diagnosis are common. One study reported an average of 7 to 8 years before patients reached clinical attention (25).

CLINICAL DESCRIPTION

The variety of obsessions and compulsions reflect the unlimited capacity of the

human mind and body. Typically, patients experience both obsessions and compulsions and most patients experience multiple concurrent obsessions or compulsions. In the minority of patients who have only one or the other (22,26) having only obsessions may be more common (27). The content of obsessions can show a wide range, but some themes are more frequent and influenced by the individual's level of development. Adolescents' obsessions typically focus on dirt and germs, fears of an ill fate befalling loved ones, exactness or symmetry, and religious scrupulousness (22). Bodily functions, lucky numbers, sexual or aggressive preoccupations, and fear of harm to oneself are less common. In adults, these remain frequent, but aggressive and sexual obsessions are more common (23,28,29).

Although any action can become a compulsion, some actions are more common. An adolescent clinical cohort (22) displayed (in descending order of frequency) cleaning rituals, repeating actions (doing and undoing), and checking rituals most commonly. Many fewer subjects reported rituals to protect themselves from illness or injury, ordering maneuvers, and counting behaviors. In adults, the most common compulsions are checking and cleaning (23,29,30). Slowness (29), counting (23), or doing things by numbers (30) each have been reported as third most common.

Several investigators (31–33) suggest that obsessions and compulsions should no longer be viewed as separate entities. These investigators used factor analysis to reconfigure Children's Yale–Brown Obsessive Compulsive Scale (CY–BOCS) symptom categories and found a four-factor model that they believed was more meaningful (34). Rather than just one homogeneous entity or as "two factors" (obsessions or compulsions), there are strong reasons to consider that OCD might be better viewed as composed of four or more subtypes. A number of investigators have now identified four-factor subtypes: (1) aggressive, sexual, religious, and somatic obsessions with checking compulsions; (2) symmetry obsessions with counting, arranging, ordering, and repeating compulsions; (3) contamination obsessions with cleaning and washing; and (4) hoarding obsessions with hoarding and collection compulsions (31–38). Mataix-Cols et al. (35) found a five-factor model that has been replicated as well: (1) aggressive checking; (2) symmetry ordering; (3) contamination cleaning; (4) sexual and religious obsessions; and (5) hoarding. These solutions are close to one another and it is not yet clear which will be the most predictive. Largely building on this work, the DSM-5 committee created a separate diagnostic entity of hoarding disorder with the OC and Related Disorder section (10).

Subsequent research, using factor analyses of symptoms without starting with Y-BOCS categories, argues for a yet more useful, "multidimensional" way of grouping symptoms and thinking about OCD symptom patterns and subtypes (39). Using latent class analysis of symptoms, Mataix-Cols et al. (39) and Nestadt et al. (40,41) identified symptom groupings that were more meaningful when placed in the context of age of onset and comorbid diagnoses. From this work there is evidence for factors

1 and 2 (above) that are associated with early-onset OCD, and a factor 4 (hoarding) that does not associate with other disorders. Furthermore, these factors show some association with comorbid disorders. Factor 2, described above, has been associated with earlier age of onset and tic disorders (32,35,42). Hoarding was more associated with axis II psychopathology (particularly obsessive-compulsive personality disorder [OCPD] (43)), social disability and social anxiety disorder (39). Subsequent work looking more closely at comorbid diagnoses also relying on latent class analysis suggests greater likelihood of comorbid diagnostic groupings, such that OCD occurs with recurrent major depression and generalized anxiety (40,42), and another that associates OCD with agoraphobia, panic disorder, and tic disorders (40).

Also, these factors correlate with treatment response (35), neuroimaging results (39,44), neuropsychologic function (45), and genetics (46,47). The course, genetic risk, neuropathology, and treatment may be different among these subgroups. For example, Alsobrook et al. (48) found that a major gene locus model was more strongly supported in families ascertained where the probands had symmetry+ordering symptoms (factor grouping II), than in probands with other symptom groupings. Alonso et al. (43) found that those scoring highly on the religious–sexual obsessions dimension fared more poorly over 2 years. Nevertheless, a serotonin reuptake inhibitor (SRI) treatment study failed to support differences in response among three of these five subtypes (35). Several other caveats were suggested by Summerfeldt et al. (33), including the possibility that “more-than-four” factor models might also be viable, that a variety of items have been excluded in the analyses performed to date that use categories from the YBOCS, and problems with using “lifetime” ratings as these are subject to recall bias.

Longitudinal studies find that symptoms often change over time and individuals’ symptoms are likely to change over the course of their illness (49). However, studies of adults reveal that, while symptoms changed, they remained within the same symptom groupings identified by latent class analysis (50). When adults with OCD were followed over 2 years, symptoms typically remained within the same symptom group (35,50). This change in symptoms with stability within symptom groupings has also been reported in children with OCD (51).

One might say that children with OCD are more *selectively* impaired than children with other psychiatric disorders. Academic and extracurricular functioning are often preserved, although the quality of peer relating may be variable (52). Studies with adults report significant impairment in social and role function (53). Koran et al. (53) noted that moderate to severe illness showed a linear correlation with social impairment. Data from clinical settings show that children with OCD have average intellectual abilities, although ascertainment bias is a factor in these reports.

On the surface, a child with OCD may appear to function well and seem relatively adapted to his or her life, but severe symptoms may be concealed while they are

enveloping the patient and family completely (53,54). It is common to learn that washing rituals consume 4 hours of scrubbing daily, dissolve an entire bar of soap at a time, leave the patient's hands worn raw and macerated, and generate huge water bills. Counting or ordering compulsions can consume half a day and virtually obstruct functioning. Repetitive rituals from night to early morning may reduce sleep to a few hours. Checking or cleansing rituals result in physical injury such as skin lacerations, ulcers, and chemical burns.

The family's reaction to the patient's symptoms is crucial. Several common response patterns may delay evaluation and treatment of OCD. Although patients are embarrassed and secretive about the content of their symptoms and the limitations they impose, serious impairment rarely eludes family members. Parents may delay seeking treatment out a false hope that symptoms will fade if everyone acquiesces or aids in performing the activities. Parent may fear stigmatization (54,55). This kind of family assistance relieves the child's symptoms only momentarily. Many times, parents cannot extricate themselves once they become involved in the rituals. Their children demand their assistance or implore them to continue. Over time, the child and parent may become pathologically entangled in rituals. When a child has sturdy development in other domains, parents find it hard to believe that he or she suffers from a serious disorder. In addition, the child's claims that the thoughts or acts are ridiculous or unnecessary can instill false security, leading parents to think that "it's just a phase." Parents with subclinical-obsessive or compulsion-like behaviors may be unable to recognize symptoms in their child and unwittingly minimize the child's impairment. Reassurance from clinicians and pediatricians who are unfamiliar with OCD may lead to mistaking severe symptoms for "normal" reactions. It is a frightening and painful moment when parents recognize that their child is ill and has lost control of his or her thoughts and actions.

ETIOLOGY AND PATHOGENESIS

Genetic Studies

Over 50 years ago, a small twin study showed that heredity plays an important role in susceptibility to OCD (56). Since then, several family studies have found a higher rate of OCD in first-degree relatives of probands with OCD versus controls (57–60). Family studies of child and adolescent probands have found even greater differences in prevalence of OCD in relatives of case (OCD) versus control probands (61,62). These findings are consistent with previous results of increased familial loading in adult probands with early age of onset (59,60). Family studies have also identified other disorders that are associated with OCD (expanded phenotype), including chronic tic disorders, obsessive-compulsive personality, hoarding, some anxiety disorders, trichotillomania, skin picking, and body dysmorphic disorder (63).

Family studies can be used to determine "recurrence risk," a clinical proxy for genetic risk for a disorder. For six available studies, the estimates of recurrence risk range somewhat with most being in the 10% to 20% range (57–62). All recurrence risk estimates for OCD are considerably higher than the estimated lifetime prevalence of OCD in the general population of 0.7% to 3.0% (16,20,64).

Heritability is the proportion of observed variation in a particular trait (e.g., obsessions) that can be attributed to inherited genetic factors in contrast to nongenetic ones. Heritability ranges from zero (no observed variation in a particular trait attributed to inherited genetic factors) to one (all observed variation attributed to inherited genetic factors). Six large twin studies of OCD diagnosis or symptoms, comparing concordance rates in monozygotic and dizygotic twins, found heritability of about 0.50, with no significant contribution from shared environment (65–70).

Recently, methods have been developed to estimate disease heritability from genome-wide genotyping data (71,72) using a statistical package genome-wide complex trait analysis (GCTA) that can estimate the lower bound of true heritability explained by additive genetic factors. A recent study of OCD using data from a genome-wide association study (GWAS) and GCTA estimated lower bound of heritability at 0.37 (73). A large proportion of heritability in OCD was present on chromosome 15. The remaining genetic variation was distributed across the rest of the genome, with almost no heritability associated with minor allele frequency of <0.05. These results, although exciting and provocative, need to be verified in independent samples of individuals with and without OCD.

Genetic linkage is the tendency of alleles that are located close together on a chromosome to be inherited together during the meiosis phase of sexual reproduction. Genetic linkage studies of OCD have identified suggestive linkage peaks (74–76), but none reached the level of genome-wide significance. Many candidate gene association studies of OCD have been conducted of genes involved in neurotransmission (e.g., serotonergic, glutaminergic) and neurodevelopment (77–80). Some of these studies have found positive associations of interest in OCD, most convincingly the neuronal and epithelial glutamate transporter gene (SLC1A1) located on chromosome 9p24, but none have consistently, or in a meta-analysis, reached experiment-wise significance (81).

Two GWASs, which compare DNA markers across the genome (the complete genetic material in a person) in people with a disease or trait to people without the disease or trait, have been reported for OCD. The International OCD Foundation Genetic Collaborative reported on 1,465 cases and 5,557 ancestry-matched controls, as well as 400 complete trios, from 22 sites (82). Although there were some interesting findings in separate case-control and trio analyses, the findings in the combined sample did not reach genome-wide significance. Of considerable interest, in the combined sample, significant enrichment of methylation quantitative trait loci and frontal lobe expression quantitative trait loci were found within top-ranked

single nucleotide polymorphisms (SNPs), possibly related to a broader role of gene expression in the brain, and the etiology of OCD.

The OCD Collaborative Genetic Association Study (OCGAS) reported on a second GWAS of 1,065 families, 1,406 patients with OCD and a population-based sample for a total of 5,061 individuals (83). Again, although there were some interesting findings, none reached genome-wide significance.

In summary, OCD is a highly heritable disorder with additive genetic factors that have yet to be identified. Future research can be expected to identify specific genes, epigenetic factors, and environmental risk. Successful genetic research will likely need larger samples of carefully selected cases and controls and improved assessment methodologies.

Imaging Studies

The aim of magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), and positron emission tomography (PET) studies of OCD is to integrate imaging of brain morphology or function with neuropsychology in the hope of improving treatment. Brain imaging during performance of neuropsychologic tasks may provide a clearer functional "map" of impairments in OCD. At this point, the map strongly implicates impairments in neuropsychologic functions related to: (a) key "executive functions," such as cognitive flexibility (e.g., the capacity to perceive multiple/alternate perspectives or assimilate and apply changing concepts) planning, and response inhibition (e.g., refraining from applying a learned "prepotent" response); (b) "evaluative functions," such as error and conflict monitoring, assessing risk and uncertainty; and (c) working memory. While imaging studies of those with OCD generally support the hypothesis of impairments in cortico-striato-thalamo-cortical (CSTC) circuitry (see below), employing diverse methods to study brain circuitry reveals a more intricate picture. Taken together, the data suggest that the CSTC circuit remains important, but the model for OCD points to impairments that go beyond this single network. Structures outside the CSTC circuit, such as parietal and dorsolateral prefrontal cortex, amygdala, hippocampus, insula, corpus callosum, and cerebellum appear to play key roles, too (84–89).

Structural Imaging Studies

Morphometric studies of adults with OCD have used region of interest (ROI) and voxel-based morphometry (VBM) designs (90). Generally they point to differences in the volume in frontal regions (cingulate gyrus) and decreased volumes in striatal regions (especially globus pallidus) and increased volumes in thalamic regions (84,91,92). However, findings using different methods do not replicate one another (93).

Meta-analyses suggest those with OCD have increased gray matter volume in the dorsomedial frontal gyrus, anterior cingulate, and bilateral lenticular nuclei and putamen (93,94) and that decreased volumes in lenticular nuclei and putamen may be specific to OCD (94) compared to other anxiety disorders. Another meta-analysis noted that, compared to healthy volunteers, those with OCD displayed decreased inferior frontal cortex and anterior insula volumes (93). This same pattern in the caudate, putamen, and globus pallidus was observed in children with OCD compared to age-matched healthy volunteers (95).

The application of the ROI method in MRI morphometry has declined in the last decade because it demands a priori hypotheses when selecting which regions will be studied (90,96). A meta-analysis (96) suggests reduced volume in the left anterior cingulate cortex (ACC) and the left and right orbitofrontal cortex (OFC) and significant increases bilaterally in thalamic volumes. No differences were noted in whole brain, ventricles, or prefrontal cortex in this analysis (96). The most robust finding was a positive correlation between increased thalamic volume and OCD symptom severity (96).

Functional Imaging Studies

Positron Emission Tomography

PET highlights specific dopamine and serotonin transporter proteins and the brain regions in which they are active and can be a powerful tool to learn about brain function. Since it is generally regarded as unethical to expose children to radioactivity exclusively for research that has no direct benefit to the participant, all these findings are from adults. When adults with OCD are compared to healthy volunteers, PET studies have replicated findings of increased activity in orbital-frontal cortex (OFC) and caudate nuclei (97–103) and increased activity in the anterior cingulate gyrus and thalamus (103).

By stratifying groups into dimensional subtypes by phenotype and employing provocation tasks, PET studies gained more specificity (104,105). Exposing OCD patients to feared stimuli during PET scanning showed increased activation in the right caudate, orbital, thalamic, and anterior cingulate gyrus (104). Unique, large differences between those with OCD plus hoarding and OCD without hoarding were noted in the dorsal anterior cingulate (105). Increased metabolism in premotor and mid-frontal regions was reported in patients with obsessional slowness (106).

Changes have also been observed in PET scans in response to treatment or spontaneous recovery. Medication responders displayed decreased right caudate nucleus glucose metabolism while no changes appeared in treatment nonresponders (107). Compared to nonresponders, responders to behavioral treatment showed increased OFC glucose metabolism (108).

Functional Magnetic Resonance Imaging

The relative safety of fMRI permits investigators to gather data from children as well as adults. Thus, comparisons can be made across development, across time (longitudinal changes), and between earlier- versus later-onset cohorts. At this point, fMRI studies of OCD point to: (1) executive function deficits implicating the dorsolateral prefrontal cortex and circuitry connecting the cingulate, frontal, orbitofrontal regions, and basal ganglia (86,87,103); (2) deficits in evaluative functions such as error monitoring, performance monitoring, and decision making pointing to deficits in the ACC, OFC, nucleus accumbens, and medial prefrontal cortex (mPFC) (88,109); and (3) deficits in hippocampal activation during specific learning tasks (110).

The anterior cingulate cortex (ACC) may play a pivotal role in OCD. The ACC is activated during conflict monitoring—the response to incoming streams of information that conflict with other information or in response to errors (111–113). Although behavioral data show *performance* on error monitoring tasks among participants with OCD to be the same as healthy controls, those with OCD show substantially increased ACC activation (112,114) and these increases in ACC activation correlate with OCD severity (112). The ACC also may be important in the distortion of appraisal functions leading to doubt and repetition (115–117) and in those who resist OCD symptoms compared to those who do not (114). In those with OCD, the anterior cingulate also showed significantly higher activation during "n-back" working memory tasks (118).

Pairing symptom profiles to fMRI scanning, Mataix-Cols et al. (44,45) presented highly specific aversive experiences to patients in an fMRI environment. The phenotypic profiles were derived from factor analytic studies and these fMRI study results showed significant symptom-specific activation in different brain regions based on clinical phenotype (44,45). Had the study omitted differentiating the groups, no differences in activation would have been observed. Such findings lend support to OCD being multiple conditions with separate, overlapping abnormalities in neuropsychologic function (39).

Diffusion Tensor Imaging

Diffusion tensor imaging (DTI) uses MRI and principles of water diffusion through brain tissue in order to observe connections between white matter regions (119). DTI studies of OCD, suggest there are abnormalities in fiber tracts in the anterior cingulate gyri and corpus callosum (119). Studies of children with OCD have raised the possibility of premature myelination in frontal regions (119) and "hyperconnectivity" in tracts that connect the thalamus and prefrontal cortex (95,120) and those that connect temporal structures such as the hippocampus and amygdala with the OFC (95). Illness severity may correlate with hyperconnectivity between the

thalamus and prefrontal cortex (95,120) and have raised the hypothesis that OCD is related to delays in, or excessively drawn out development of those white matter tracts (120).

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) can show metabolic activity of the brain by measuring the density and activity of glutamate, N-acetylaspartate (NAA) (a signal of neuronal destruction or injury) and glycerophosphocholine plus phosphocholine (Cho) (a signal of membrane phospholipid metabolism). Studies of drug-naïve children with OCD suggest increased cells or abnormal myelination in medial thalamus and right prefrontal cortex (121). Positive correlations between OCD severity scores and NAA levels in the right prefrontal region were also observed (121). MRS studies of glutamate showed decreased levels in the ACC (122). In one study, elevated glutamate levels in the caudate nucleus, measured by MRS, normalized after responding to treatment with paroxetine (123).

Abrupt-Onset OCD

There are cases of children having a dramatic, abrupt onset of obsessive-compulsive symptoms. While this presentation was once thought to be tightly associated with group A beta-hemolytic streptococcal (GABS) infection, a series of studies now cast doubt over this relationship (124). Abrupt onset can be seen following traumatic brain injury (125).

Swedo et al. (126) termed the specific GABS-related syndrome PANDAS and proposed that it, like Sydenham chorea, arose from an autoimmune cross-reaction of streptococcal bacteria and basal ganglia structures. Subsequent work raised such serious doubts about PANDAS criteria (127) and theory behind it (124,128) that it has now been supplanted by another syndrome termed PANS (127) or CANS (129) that emphasizes abrupt onset, additional symptoms that arise concurrently, and the absence of medical conditions known to cause OCD (127,130). Therefore, caution is in order when considering clinical intervention for a child who might have abrupt-onset OCD. Children or parents of children with OCD, commonly report abrupt onset or exacerbation of symptoms with infection. Since viral and GABS infections are so common in the pediatric population, one might expect a frequent overlap in children with OCD. Several reviews provide details on the differential diagnosis and evaluation of PANS (127,129,130). Considering an autoimmune mechanism is only relevant for the highly specific pattern of acute-onset and concurrent-onset additional symptoms (130). In addition, there is insufficient evidence to support use of antibiotic prophylaxis, immunoglobulins, or plasmapheresis as a standard treatment for patients with PANS or abrupt onset of OCD (129–132) and, at this time,

recommended treatments for abrupt-onset patients are the same as for all OCDs (132).

The Cortico-Striato-Thalamo-Cortical Circuit

Neuroscience and clinical psychiatry are closely intertwined. Explorations of the pathophysiology of serious mental disorders has increased our understanding of networks operating in the central nervous system, and the study of these circuits and networks reciprocally increases our understanding of pathophysiology of psychiatric disorders. From the study of disorders we learn about the development and functional interconnections of the central nervous system. New knowledge about the brain extends our understanding of the pathophysiology of brain disorders, our ability to treat symptoms, and our understanding of the relationship between disorders. OCD is among the best paradigms of this reciprocal process. Once it was shown that medication could improve OCD (133), the way was opened to identifying biologic mechanisms that predispose to it, precipitate it, and maintain it. In turn, this has advanced our general understanding of neural networks.

The conceptual model of OCD integrates neuropsychologic, anatomical, neurochemical, and electrophysiologic findings (107,134–138). It proposes somatotopically organized connections and circuits between brain structures as CSTC circuits that subserve planning, execution, and termination of voluntary movements (84,91,139).

This "basic model" (84,89,91,134,135) proposes that frontal cortical and limbic structures have excitatory effects on striatal structures via glutamatergic efferents. These striatal structures, including the caudate nucleus, putamen, nucleus accumbens, and olfactory tubercle, project to the internal and external globus pallidus. From the internal globus pallidus, inhibitory efferents using gamma-aminobutyric acid (GABA) have tonic activity at the thalamus. Consequently, *increased* striatal activity *decreases* inhibitory activity (or creates disinhibition) at the thalamus. Increased activation of thalamic nuclei produces excitatory transmission to cortical structures and then movement.

However, this basic model has required modification in three ways. The first modification introduces separate "direct" and "indirect" pathways between the striatum and the thalamus. The direct pathway is so termed because efferents pass directly from the striatum to the thalamus, exerting a disinhibiting (activating) effect. Conversely, the indirect pathway sends a variety of efferents to subthalamic nuclei, which in turn send efferents to both the globus pallidus externa and globus pallidus interna. The indirect pathway moderates activity in the thalamus (134,135,137).

The second modification proposes two parallel systems from the striatum, one related to the dorsolateral region and the other the ventromedial region. Input to the ventromedial region is largely from limbic structures, whereas dorsolateral regions

receive input from the dorsal cortex. From the striatum, both direct and indirect systems send information to the thalamus. Activation of the dorsolateral system can produce either disinhibition or inhibition of the dorsal thalamus via the direct or indirect system, respectively. Activation of the ventromedial pathway only results in inhibition of the dorsal thalamus (134,137). Balance in the activity between the dorsolateral and ventromedial striatal systems is crucial in maintaining control (89). In OCD, increased tone in the pathway from limbic cortex to ventromedial striatum excessively activates the direct pathway, decreasing inhibition, and producing symptoms (overactivation) (134,137). SRIs attenuate afferents to the ventromedial pathway at the level of the striatum. Direct pathway tone decreases relative to the dorsolateral system and equilibrium is restored. Baxter (137) has hypothesized that behavioral treatment works by increasing tone in the dorsolateral system relative to the ventromedial system. Increasing tone in dorsolateral system restores the balance.

The third modification is to understand the influence of structures outside the CSTC circuit, including parietal and dorsolateral prefrontal cortex, amygdala, hippocampus, insula, corpus callosum, and cerebellum (84–89) that clearly play either a direct role in symptoms or an influential role in the functions of the CSTC circuit.

This model is compatible with the variety of neurochemical findings. First, it accounts for the efficacy of SRIs. Serotonin selectively activates GABA and reduces glutamatergic output from limbic efferents to the ventromedial caudate. Consequently, serotonergic augmentation substantially reduces activation in the ventromedial system.

Another dimension is the relationship between serotonin and dopamine. Dopaminergic inputs distributed throughout the caudate nucleus have downstream effects on the thalamus (134,135,137). There is a gradient of D1 and D2 receptors across the caudate. Higher concentrations of D2 receptors are observed in the dorsolateral caudate and decrease as one moves toward the ventromedial region. Conversely, a lower concentration of D1 receptors in the dorsolateral caudate increases as one moves toward the ventromedial region. Blockade of D2 receptors would have a greater effect on dorsolateral circuitry and produce a decrease in both direct and indirect pathway activity. This too would change the balance in activity between the dorsolateral and ventromedial regions.

EVALUATION

Clinical Evaluation

The treatment of children with OCD must begin with a thorough evaluation by a mental health clinician who is experienced in the assessment, differential diagnosis, and treatment of this condition. Children usually feel embarrassed about their

symptoms and minimize impairment and underreport their symptoms to their parents (140). Frequently, children fear that their symptoms are bizarre and “crazy.” They are most likely to describe symptoms to a clinician who resists confrontation, conveys acceptance, and respects privacy; it takes time for the patient to reveal his or her fears fully. Consequently, assessment usually cannot be completed in one meeting (132).

An adequate evaluation of OCD samples multiple sources. It is desirable to gather history from the patient alone, from his or her parents alone, and from the family together. Helpful information can be obtained from teachers on academic performance, peer relationships, areas of impairment, and tasks presenting special challenges. Siblings may provide valuable information on family responses to the patient.

The objectives of individual meetings are to ascertain the patient’s developmental level, extent of impairment, and associated diagnoses and symptoms. The clinician should discover the patient’s strengths and weaknesses, fears and aspirations, achievements and disappointments. Symptoms often ruin life at home, school, and work. They damage peer relations and self-image. Therefore each of these domains should be assessed. When asked directly, patients may also talk about OCD symptoms that are exhibited by others at home.

Thinking about the long-term relationship with the patient is important from the start. A clinician may feel pressure to overpower denial, root out secrets, and unmask obsessions but doing so could sacrifice the patient’s trust and confidence. A clinician can become so entangled in an aggressive pursuit to unearth symptoms and penetrate concealment that he or she loses the relationship.

Information from family members can allow one to learn the extent to which symptoms interfere with the patient’s life and if there are ways the family is unwittingly facilitating symptoms (54,55). The family evaluation should yield information about family dynamics and how the patient’s illness influences the family. It is helpful to learn the significance of the patient’s symptoms to the parents, how the parents understand their child, and what the family’s responses to the patient’s behaviors have been. These aims are most readily accomplished by direct observation and interaction with the family. A critical question is whether concomitant family treatment may be needed to change patterns of communication, patterns of interaction, and other sources of conflict. It is valuable for parents to obtain treatment when their psychopathology is exacerbating the patient’s condition.

Meeting with parents alone is pivotal for gathering sensitive information and educating them about OCD. Personal information about each parent and their marriage, medical and psychiatric history, disappointments, concerns, and frustrations, and confidential information about the history in extended family members should be obtained without the patient. Meeting with parents alone is important for teaching and reassuring them about their child’s illness. A parent may

fear that their child is psychotic or untreatable, feel guilty that they have caused their child's condition, fear that the clinician is going to blame them for their child's difficulties or compete with them for their child's affection (55). Parent-only meetings are opportunities to reassure and solidify a collaborative relationship.

Although a comforting atmosphere fosters discussion of symptoms and stresses and assists in monitoring progress, it may not yield a thorough overview of strengths and difficulties. Standardized instruments do not convey the quality of difficulties or the impact of symptoms on the patient and others, but they are more effective for general assessment and screening. They also permit the clinician to assess severity in comparison with clinical populations. Two instruments have been used with children and may assist a general clinician in this way: the Leyton Obsessional Inventory—Children's Version (LOI-CV) (141,142) and the Children's Yale–Brown Obsessive Compulsive Scale (CY–BOCS) (143–145).

Differential Diagnosis

Table 5.5.2.1 offers a partial list of disorders in which obsessions or compulsions are seen. Often with chronic OCD one sees comorbid major depression or at least symptoms of fatigue, helplessness, and hopelessness. Though rare, OCD can arise as a consequence of specific brain disorders ("organic brain syndromes") (146).

When there are disorders comorbid with OCD, DSM-5 requires that the content of the obsessions not be restricted to any comorbid disorder or better explained by another disorder. Although this eliminates some difficulties, it creates others. It can be difficult to discern how related or unrelated a symptom may be. Therefore, clinicians are obligated to conduct thorough diagnostic assessments in order to detect all active comorbid conditions (147). Neglecting to do so will lead one to miss findings that are relevant to treatment and prognosis (148). Similarly, if research studies are to be generalizable and valid, investigators are obligated to provide comprehensive descriptions of their sample subjects (147). Care should be taken not to equate subclinical obsessions or compulsions with threshold OCD, especially in adolescents. Subclinical phenomena appear to be stable features that do not interfere with development and functioning (25) and are seen in as much as 80% of the population (149).

One might mistake OCPD for OCD. Most children with OCD do not have OCPD, although there is some suggestion they may be at higher risk than others for developing OCPD in adulthood. In OCD and OCPD, patients may have rigid routines, needs for orderliness, hoarding behaviors (that are subthreshold for hoarding disorder), and indecisiveness that fluctuate in severity and escalate under stress. However in those with OCPD, these behaviors typically do not cause anxiety or subjective distress. The impairment in OCPD is a product of patterns of interpersonal interactions and a detached, inflexible behavior toward others, rather

than circumscribed, internally distressing experiences and symptoms that characterize OCD.

TABLE 5.5.2.1

DISORDERS MANIFESTING OBSESSIONS AND/OR COMPULSIONS

Anorexia nervosa
Autism spectrum disorder
Body dysmorphic disorder
Delusional disorder (all types)
Depression
Hypochondriasis
Obsessive-compulsive personality disorder
Organic mental disorder[a]
Panic disorder
Phobias
Posttraumatic stress disorder
Schizophrenia
Schizotypal personality
Somatization disorder
Somatoform disorders
Trichotillomania
Tourette disorder

[a]Specifically arising from CNS trauma, tumors, toxins.

Conversely, patients with OCD generally are not emotionally cold, unexpressive, stingy, or especially rigid about moral or ethical matters. Furthermore, list making and rigidity about schedules or time are uncommon among compulsions reported by patients with OCD (23).

In relation to OCD, insight means the ability to understand that urges and/or obsessions originate in the patient's mind and are not imposed by external sources, or that fears are excessive and senseless. When insight is compromised, it can be difficult to differentiate psychosis from overvalued ideas. Some patients with OCD balance precariously between delusional conviction and insight. At some moments their compulsive behaviors seem logical and necessary to carry out and, at others, these same behaviors are viewed as senselessness, excessive, or grossly distorted (9). DSM-5 permits the diagnosis of OCD when schizophrenia or delusional disorders are present. Comorbid combinations like these can further complicate specifying the patient's level of insight. Clinicians should be mindful of comorbid diagnoses when patients have little or no insight since lack of insight in OCD is associated with a poorer prognosis and should influence treatment strategies (114).

Laboratory Studies

There are no pathognomonic laboratory findings in OCD. Appropriate laboratory evaluation follows from the findings of the history, physical, mental status, and

psychological examination. An electrocardiogram, complete blood count with differential and baseline blood chemistries, including electrolytes, as well as liver function tests, blood urea nitrogen, and creatinine may be necessary before commencing somatic treatment. Measures of serum copper for Wilson disease are unnecessary in the absence of psychotic symptoms or physical findings of tics or chorea. CT or MRI scanning is warranted only when focal neurologic findings are discovered. Electroencephalography is indicated only when other features suggest a seizure disorder.

If there are concerns about a child's cognitive abilities, standardized Intelligence tests, such as the Wechsler Intelligence Scales for Children edition IV or V (WISC-IV or WISC-V) or the Differential Abilities Scale (DAS) are appropriate.

Severity measures of obsessions and compulsions are discussed below. In addition, the parent-on-child version of the Child Behavior Checklist (CBCL) (150) or the Behavior Assessment System for Children (151) may help discover other maladaptive behaviors.

TREATMENT

Although diverse treatments have been used to help children with OCD, only cognitive-behavioral therapy (CBT) and medications have been systematically studied. CBT is widely regarded as first-line treatment (132,152,153). Adjunctive family treatment is often necessary (132,152,153). In rare circumstances, inpatient hospitalization may be necessary.

Family Support and Illness Education

Whichever modalities will be used, the clinician's relationships with the patient and parent(s) are paramount. First, most children with OCD are apprehensive and secretive. In many cases they are embarrassed or anxious about what others will think of their symptoms and have mixed feelings about receiving treatment. The relationship with their treating clinician offers reassurance, reduces anxiety, promotes discussion, and furthers the treatment. Second, many patients are uneasy discussing their thoughts or rituals because the content may be scatologic or sexual. Clinicians should strive to foster a relationship in which patients feel that the clinician will not "judge them," will understand the distress they experience and can be trusted with the "unacceptable" content of their symptoms. Third, when treatments require time to take effect or produce significant anxiety, the strength of the relationship with the clinician is what sustains the work. Fourth, treatment may not lead to complete remission; many patients will have a chronic, though hopefully substantially less severe, course. Thus, the treatment relationship with the clinician may need to be maintained over years.

After the diagnosis is established, it is critical to review the causes, nature, and course of illness with the patient and his or her parents. The clinician should explain the relevance of comorbid features for interventions and prognosis. This may need to be reiterated during the course of treatment. It is helpful to the family and patient to understand that the course of OCD may be chronic. In light of this, the objectives of treatment are to reduce the interference in the patient's life caused by symptoms and to support the child's optimal development. It might be unrealistic to expect that symptoms will vanish. Furthermore, part of the evaluation is to explain how the family can best support the patient and to find the support they need to sustain themselves for a potentially lengthy treatment. Seeking risk factors for family accommodation that might compromise treatment is also critical at this early stage (154,155). While it is possible that symptoms will linger, clinicians have every reason to be encouraging and optimistic that treatment will lead to a significant reduction in impairment.

Cognitive-Behavioral Therapy

CBT is the first line of intervention for most children with mild to severe symptoms (132,152,156–159). CBT has been systematically investigated for children with OCD (152,157–159) (employing multiple rigorous tests) (161). There is ample support for the efficacy of CBT (157,158,160–163).

The most investigated type of CBT for OCD is graduated exposure with response prevention (ExRP), a less aversive version of "flooding with response prevention" (164,165). March et al. (164) studied CBT using ExRP with 15 children; 9 (60%) achieved at least a 50% reduction in symptoms that was sustained for 18 months.

Expanding on this work, the Pediatric OCD Treatment Study (POTS) (163), compared the efficacy of ExRP with sertraline treatment. POTS emphasized an adequately sized treatment cohort, standardized assessments, random assignment, control groups, and strict fidelity to treatment techniques (163). The response rates to sertraline-alone and CBT-alone were the same, roughly 40% (163). This was a significantly lower response rate to ExPR than that reported in less rigorous studies (163). Importantly, there were substantial site-specific effects in POTS. CBT-alone at the University of Pennsylvania (UPenn) yielded superior results to CBT-alone at Duke, while sertraline-alone at Duke was superior to sertraline-alone at UPenn. However, combined CBT-plus-sertraline and placebo-alone showed no between-site differences. de Haan et al. (161) also compared ExRP to medication (clomipramine), though on a much smaller scale, and found these treatments equally effective.

POTS II compared the efficacy of combined treatment using ExRP + medication, with medication-alone (166), and explored what part of ExRP treatment might be pivotal. In order to perform a more rigorous test of the importance of therapist-assisted exposure, 124 children were randomly assigned to 12 weeks of an SSRI-

alone (mostly fluoxetine or sertraline), full-CBT + SSRI, or CBT-instruction + SSRI, which had no exposure sessions. The rate of responders to full-CBT + SSRI was 68% compared to the 30% to 34% in the other arms. SSRI-alone did not differ from CBT-instruction + SSRI.

Since CBT can have many different elements such as "psychoeducation, socialization to a theoretical model, parent training, anxiety management techniques," Bolton and Perrin also explored whether ExRP was a critical element (167). They studied 20 patients, randomizing them to waitlist or a modified ExRP that had minimal cognitive or psychoeducational components. Though a smaller study, ExRP was significantly more effective than the waitlist condition. Conversely, Williams et al. (168) explored an approach that, rather than using exposure techniques, draws on cognitive interventions that encourage patients to take responsibility for their thoughts, and to think about and use strategies to manage them. A pilot study of older children using this method found a large effect size although response or remission rates in this small cohort (*n*=21) were not reported (168).

The scarcity of well-trained expert therapists and the intensiveness of the treatment using ExRP have led investigators to explore modifications in the technique to boost the efficiency of this modality without compromising efficacy. Storch et al. (169) compared the efficacy of a shorter-term, intensive treatment ("90-minute psychotherapy sessions held 5 days/week for 3 weeks") for children, to conventional, 14-session weekly CBT treatment. There was no difference between the groups in the rate of remission immediately following and 3 months after treatment (169). Asbahr et al. (170) compared a 12-week group therapy ExRP to treatment with sertraline. The treatments were equally effective with a 75% response rate, but the rate of relapse 9 months after treatment was significantly lower in the group-CBT recipients. The method used to analyze the data limits the validity of these findings. The trial of sertraline was short and the majority of those in group-ExRP were not fully compliant with treatment.

When treating younger or more developmentally immature children, ExRP may be intimidating and outstrip their cognitive abilities for abstract reasoning and self-observation. In addition, for children with OCD, there appears to be a direct correlation between the extent to which their parents make accommodations (such as assisting their child with carrying out rituals or facilitating avoidance of situations that evoke anxiety) and greater functional impairment and treatment resistance (155,171). Recognizing that such children rely on their parents so much, investigators explored including parents directly in the ExRP treatment. Several studies have demonstrated efficacy of ExRP for children when modified in this way (162,172–174). Treatment conducted with this modification shows improvement in roughly 60% of participants with roughly 40% in remittance (173).

Storch et al. (175) explored the efficacy of web camera–delivered family-based ExRP treatment using random assignment to active treatment or a waitlist control.

Significant differences were seen in active treatment and gains were sustained after 3 months; a large effect size was observed.

In a third POTS study, termed POTS Jr (176) 127 children, 5 to 8 years of age, were randomly assigned to 14 weeks of family-based ExRP (akin to what was used in POTS II, above, but with much greater emphasis on psychoeducation and parent-based skills plus simpler behavioral tasks) or an active control of family-based relaxation training. Family-based ExRP was superior to the control condition; rate of remission was 72% for those in FB-CBT and 41% for the group with relaxation training (176).

A review of the research and the treatment guidelines on CBT for OCD highlights two characteristics that strongly influence treatment efficacy. CBT must closely adhere to an established manual that includes ExRP elements. Also, efficacy is correlated with clinicians' depth of training in CBT for OCD and their experience with it.

Pharmacologic Treatment

It is widely known that a variety of agents that inhibit serotonin reuptake appear to be useful in the treatment of OCD. The claims for efficacy that are ubiquitous in advertisements and media may mislead patients to conclude that anyone with OCD will achieve remission by taking medication. It is helpful to inform patients at the outset that reliable studies have shown 40% to 50% of drug-naïve patients experience a reduction of 25% to 40% severity in symptoms. This is important when obtaining consent prior to treatment and in helping patients understand why they may continue to experience symptoms after a course of treatment.

The clinician also should be mindful of comorbid psychopathology when choosing medications. Coexisting panic disorder, psychotic or schizotypal features, depression, or Tourette disorder might steer toward classes of drugs and specific agents with demonstrated efficacy in these conditions and with OCD.

Determining whether a patient has responded to a medication requires that sufficient doses be given for a sufficient duration. This is separate from the time needed to gradually increment to the maximum tolerated dose. A majority of studies suggest that an adequate trial has been offered when the patient receives either the maximum allowable dose or the maximum dose that the patient can tolerate for at least 4 weeks. An important consideration in weighing efficacy is adherence to the prescription. Family accommodation affects adherence to both psychological and pharmacologic treatments and commonly results in missed doses or to taking an improper dose (155,177). Gradual dose reductions are necessary to avert withdrawal reactions when discontinuing those medications with shorter half-lives such as fluvoxamine and sertraline.

The most studied medications in the treatment of OCD are potent SRIs. While we

refer to these drugs as SRIs, it should be kept in mind that all of them affect other neurotransmitter systems, too and, as a result, have different side-effect profiles. Controlled, blinded studies in children have used clomipramine (178,179), fluoxetine (180,181), fluvoxamine (182), sertraline (163,183,184), paroxetine (185), and citalopram (186,187). Of these, neither paroxetine nor citalopram has FDA indications for OCD.

Mataix-Col et al. (35) attempted to predict the outcome to placebo or active agents by stratifying the cohort according to factor-analyzed subgroups (see above). Their results suggested that the hoarding group was less likely than other subtypes to respond to SRIs. The other factor groups were not different from one another in their responsiveness to SRIs.

A meta-analysis of 12 studies of pediatric OCD employing SSRIs or clomipramine concluded that response rates among the SRRIs were comparable, and clomipramine was superior by a significant margin (188). Nevertheless, the side-effect profile and tolerance for clomipramine continue to place it outside consideration as the first-line pharmacologic treatment for pediatric OCD (189).

Augmentation Strategies

Between 40% and 50% of individuals with OCD do not respond to adequate trials of SRIs (163,190,191). The failure of response to one SRI agent does not predict failure of response to another, and side effects from one agent do not predict side effects on another. For this reason, it is important to offer adequate doses for a sufficient period of at least two and even three agents before moving on to augmentation strategies.

While the use of polypharmacy is generally to be avoided, an augmentation strategy may become necessary. There are randomized, double-blind placebo-controlled trials (RBDPCT) in adults suggesting that augmentation with haloperidol, risperidone, and aripiprazole may be useful (192,193); studies do not show benefits with olanzapine or quetiapine (192,193). A trial comparing aripiprazole versus risperidone added to existing medication for children with tic-related OCD showed both drugs were equally beneficial (194).

Use of atypical antipsychotic augmentation remains controversial (192); adding CBT to SRI was more effective than risperidone or pill placebo in a study of adults (195). Furthermore, in children who had not benefitted from an initial course of CBT, a randomized trial that extended CBT or added sertraline showed equal, and significant benefit (196). N-acetylcysteine is metabolized in the body into cysteine, a precursor to glutathione. The effects of NAC are diverse and yet to be understood but are likely to influence glutamate function (197). In adults (198) a small RBDPCT add-on study suggested NAC may be useful but no studies have been done in children with OCD.

Along the same lines, riluzole, a glutamate modulator, was assessed in an

RBDPCT in children and failed to demonstrate a difference from placebo (199).

Partial Hospital and Inpatient Treatment

Hospitalizing patients to evaluate their symptoms is rarely feasible nowadays unless it can be justified by compelling concerns about safety. However, acute hospital care may be necessary and useful when patients or families are in crisis. Hospitalization may help when symptoms are severe and spiral out control, the family's capacity to support the patient is thoroughly depleted, compulsions are dangerous, or there is ongoing severe impairment despite a sufficient course of treatment. While clinicians are likely to feel pressed to initiate additional interventions in a crisis, in OCD such crises typically are the aggregation of chronic stressors that also are important to understand for the ongoing treatment.

In a crisis, partial (or day treatment) hospitalization can be a constructive alternative to inpatient care or dramatic changes in outpatient treatment. Furthermore, should partial hospital treatment fail, inpatient treatment may be more acceptable. Partial or inpatient hospitalization can reduce the pressure on parents and the patient to contain symptoms that are out of control. Also, it may provide rapid, objective assessment of the severity of the patient's impairment outside the home, facilitate integration of psychological, family, and pharmacologic treatments, and reduce stresses and anxiety of school or home.

COURSE AND OUTCOME

The mean age of onset of OCD is 19.5 years and the average duration of illness is 9 years (20,21). Skoog and Skoog (200) studied the natural history of 251 adult patients over 30 years. In this cohort, 29% had onset before age 20, 40% between ages 20 and 29 years, and 32% after age 30. Yet others report that 40% onset before age 20, and an average age of onset in the early 20s (201). In the ECA, the mean onset was 20.9 to 25.4 years of age (18). Others note that age of onset of OCD is almost exclusively before age 18 (59).

Outcome from an episode of OCD can range from complete, permanent remission to continuous decline. Points along this continuum include complete remission with discrete recurrent episodes, partial remission (chronic low to moderate symptoms), and partial remission punctuated by severe flare-ups (202).

Generalizing conclusions about outcome to all patient groups based on data derived from self-referred patients is unreliable and obtaining reliable outcome data from community samples is very challenging. Thus one study of adults reported "continuous" illness with fluctuating severity was the most common (84%) and a deteriorating course in 15% (23). Yet others (29) reported 2-year spontaneous remission rates of 65%, and another reported greater than 80% improved on all

measures (203). Outcome based on hospitalized patients gives a rate of only 30% who were “greatly improved” (30,202).

Skoog and Skoog’s (200) study of adults reported that intermittent illness (periods of OCD interspersed with completely symptom-free periods) occurred in 56% of their cohort, followed by chronic illness (continuous, unremitting severity lasting over 5 years) in 27%, and an episodic course (one episode of illness lasting <5 years) in 17%. In this 40-year longitudinal study, 83% of patients improved, 48% improved clinically, and 20% recovered completely (200).

A prospective study of a nonclinical public high school adolescent cohort resampled them 2 years after they were first identified with either OCD (n = 16) or “subclinical” obsessions or compulsions (n = 10) (204). Those with “subclinical” obsessions and compulsions did not worsen; only 1 of 10 developed OCD. Only 5 of 16 (31%) initially diagnosed with OCD met criteria 2 years later. Furthermore, a measure of impairment of those diagnosed with OCD diminished by 30%, beneath the cutoff for clinically significant impairment. The authors wondered if this reflected actual improvement or methodologic unreliability. The most likely predictors of an OCD diagnosis were previous diagnosis of OCD and presence of another psychiatric diagnosis with OC features. This could reflect the concept of OCD as a heterogeneous disorder with waxing and waning symptoms, and a relatively more benign, nondeteriorating course. The 69% recovery rate approaches the spontaneous adult remission rate reported by others (29,202).

Taken together for pediatric OCD, the general prognosis that emerges is of a less severe disorder than was reported in studies before 1990 (205–207). Sixty percent of children will improve to a level that they no longer meet criteria for the disorder and roughly two-thirds of those will recover (40% overall). Although this is certainly encouraging for the majority, those with co-occurring disorders, earlier onset, longer duration of symptoms, and poor psychosocial functioning are not as likely to recover. Poor response to medication, presence of tics, and parental psychopathology also predict a poorer outcome (208).

FUTURE CHALLENGES AND RESEARCH

On the treatment front, interest in OCD has produced well-informed clinicians with greater diagnostic and treatment skills. Self-help organizations, such as the International OCD Foundation (https://kids.iocdf.org; info@iocdf.org; International OCD Foundation, Inc., P.O. Box 961029 Boston, MA 02196), have informed the public and are bringing down the isolation and embarrassment experienced by persons with OCD. As organizations and clinicians educate the public, those who fear treatment or have been disappointed in previous efforts are now receiving more effective treatment and achieving some relief. A majority of seriously ill patients will improve if they receive specific CBTs or family cognitive-behavioral treatments,

and, to a smaller extent, medications. Nevertheless, there is still a need to improve treatments. Current treatments produce limited success in 30% to 40% of patients (209). Hoarding remains the most refractory symptom and disorder (210).

Too many persons with OCD continue to suffer in secrecy. Epidemiologic studies remind us that the majority of persons with OCD do not obtain consultation or treatment. Too few clinicians are schooled CBT techniques (152,211). Vigorous effort to inform the public and assist primary care clinicians in recognition of OCD is still needed. Training clinicians in effective treatments, extending treatment and neuroscience research, and improving outreach and public education are the greatest challenges now.

On the research front, imaging techniques may yet illuminate structural relationships and link neuropsychologic and anatomical findings in ways that will advance more successful treatments. OCD also continues to hold out opportunities to learn about links between genetic endowment and environmental experience (212).

CHAPTER 5.5.3 ■ TRICHOTILLOMANIA AND EXCORIATION DISORDER

KENNETH E. TOWBIN

François Henri Hallopeau coined trichotillomania (TTM) from the Greek words for "hair + pulling + madness" in 1889 (1). TTM, excoriation disorder (ED), and obsessive-compulsive disorder (OCD) share a feature of repetitive behavior yet there may be more than this visible similarity between them (2,3). With publication of DSM-5, all three are part of a larger group of obsessive-compulsive and related disorders (OCRDs) (4). The DSM-5 concept of this obsessive-compulsive spectrum draws on shared characteristics of impulsive and repetitive behaviors and includes OCD, body dysmorphic disorder, hoarding disorder, TTM, and ED. The decision to place these together is controversial, particularly for TTM and ED (5,6). The rationale for encompassing them into a larger group of OCRDs grew from data suggesting (1) increased rates of hair pulling (HP) and ED among those with OCD, and of OCD among those with TTM or ED, (2) the shared phenotypic similarity of repetitive (compulsive) behaviors, preceded by urges, and followed by temporary relief, and (3) increased rates of these disorders among first-degree relatives of those with OCD and TTM (7–9). Furthermore, there are reports that childhood-onset OCD is a risk factor for TTM (10,11) and that TTM often has its onset in childhood and adolescence (8–11). Some have suggested that TTM and ED are alternative manifestations of the same genetic predisposition (3).

The DSM-5 diagnostic criteria for TTM and EM are essentially the same (4). Both require a behavioral component—recurrent HP (or skin picking) to the point of hair loss (or skin lesions), *and* a psychological component—repeated attempts to decrease or stop this behavior. In addition, there are the usual provisos that the problem must lead to distress or impairment in domains of social, occupational, or other areas of function in the person's life, not be attributable to a medical condition, and not be better explained by another condition (DSM-5, APA). Some investigators view these criteria as excessively restrictive (12–14).

TRICHOTILLOMANIA

The prevalence of HP without psychological components is 4% to 6% in the general population (13–15), compared to the 0.6% to 1% prevalence reported for TTM (13–15). Females are more common in some clinical samples while others report an equal distribution by gender (15). The age of incident peaks in early childhood and adolescence (13–15). Forty-five to 55% of TTM/HP patients report a childhood (before age 18) onset (16).

Data showing that HP and TTM have a similar course, prognosis, genetic risk, and

treatment response would provide more convincing biologic evidence of a close relationship. TTM and HP are often comorbid with OCD (16–18). Four to 35% of patients with OCD report lifetime histories of TTM/HP (18–22), and 13% to 16% of those with TTM/HP report lifetime histories of OCD (16,23,24). Also, TTM and HP both are commonly associated with tic disorders (10,12,18,20,21,25). As with tics, TTM/HP appears to be particularly associated with early-onset OCD (12,18,20). TTM/HP is also associated with hoarding (26). Most studies have relied exclusively on clinical populations at risk, producing an erroneous, biased association (27). However, two studies drawing on nonreferred, community samples suggest an association may exist (13,14).

There is evidence that TTM/HP may show genetic associations with OCD (12,21) though the data are mixed. The first studies drew data from small and relatively unrepresentative samples (12,13). Bienvenu et al. (21) conducted a controlled family study of 88 adults with rigorously diagnosed OCD and their first-degree relatives. There were few individuals with TTM in the entire cohort. Comparing patient probands to healthy controls, rates of TTM were not statistically greater. Comparing first-degree relatives of probands to first-degree relatives of healthy volunteers (HVs), the rates of TTM were not significantly different. The study also ascertained rates for other "pathologic grooming behaviors" such as pathologic skin picking and nail biting. Only skin picking was statistically significantly greater among OCD probands compared to HVs. The rates for all grooming behaviors were not elevated in first-degree relatives of OCD patients compared to relatives of healthy controls (21). However, a replication study drawing on a larger number of patients and of first-degree relatives showed that, compared to a healthy control population and their relatives, the rate of TTM in those with OCD was greater both among patients and among their relatives (28).

There are preliminary, but few, neuropsychological data on TTM and there are many fewer data from pediatric patients. Compared to adults with OCD, adults with TTM display some overlapping but not entirely congruent patterns of neuropsychological impairments (29–31). One study (29) examining age- and IQ-matched adults with OCD, TTM, and HVs reported no differences between groups on measures of attention, memory, organization (verbal and nonverbal), visual–spatial abilities, and concept learning (29). The only differences were that those with TTM showed increased perseveration errors, suggesting cognitive inflexibility, compared to those with OCD and HVs, while compared to the other groups, patients with OCD showed impaired learning from feedback based on the Wisconsin Card Sort (29). Chamberlain et al. (31) examined a purported endophenotype for OCD related to "strategy implementation," which integrates cognitive functions and motor inhibition (30) and are, in turn, closely tied to the orbitofrontal striatal circuitry described for OCD (Chapter 5.5.2). Using the Stop Signal Task, to measure capacity to suppress impulsivity, these investigators (31) compared patients with only OCD to those with

only TTM and HVs. They found that adults with TTM displayed abilities in strategy implementation equal to HVs (31), and significant deficits in motor inhibition compared to patients with OCD and HVs (30). In contrast, a study with pediatric patients (32) found that, after controlling for both age and symptoms of attention-deficit hyperactivity disorder, compared to HVs, children with TTM had *greater* inhibitory control.

Morphometric MRI studies have studied only a small number of patients (33–35). Taken together they suggest that compared to HVs, women with TTM have decreased volumes in the left frontal cortex. Interestingly, in contrast to reports on patients with OCD, there are no differences in the caudate or in white matter structures. A diffusion tensor imaging (DTI) study (36) of TTM showed reduced connectivity between white matter tracts that connect the orbital frontal cortex and anterior cingulate cortex, the left presupplemental motor area, and the left temporal lobe.

The relative rarity of TTM has hampers how much we know of its course and treatment. As with many uncommon disorders, the patients who come to clinical attention can be an inaccurate reflection of the entire range of the disorder, are likely to be severely impaired and to suffer from comorbid conditions such as depression or anxiety disorders. The best evidence suggests that TTM has a chronic waxing and waning course. One study (37) followed the course of only 14 participants after CBT; 12 of 14 individuals were considered responders at the end of treatment. However, at an average of 3 years 9 months follow-up, only 4 of 13 were still considered responders. When compared to the group of 10 individuals who initially refused treatment, there was no difference in overall response rates between treated and untreated groups (37). Another study (38) followed the course of 63 individuals who had participated in a “state-of-the-art” treatment study. After a mean of 42 months, 51% were still in treatment and 27% were not. Thirty-three (52%) participants considered themselves treatment responders while 16 (25%) improved with CBT alone. The investigators reported that higher rates of depression correlated with better outcome (38). However, in a subsequent follow-up of the same cohort (39) some 30 months later, 61% were still in active treatment for TTM and only 37% considered themselves treatment responders. While the first follow-up point reported improvement in self-esteem, depression, and anxiety, this progress had virtually disappeared at the second follow-up despite improvements in HP (39).

Pharmacotherapy offers modest improvement for TTM. Among all agents, serotonin reuptake inhibitors have been the most studied (38,40–44). Few randomized controlled studies have been conducted and rates of improvement have been disappointing. While open-label studies report rates of improvement of 30% to 60%, two placebo-controlled trials showed no significant difference from placebo (41,43). Generally, the response to SSRIs appears to be lower in TTM than what treatment trials report for patients with OCD (44).

Two small studies employing randomized assignment demonstrated superiority of

CBT to medication (one study using clomipramine, the other fluoxetine) (42,45,46). In order to explore whether these gains could be maintained, Keijsers et al. (45) performed a 3-month and then a 2-year follow-up on 28 participants, some of whom were previously in the CBT versus fluoxetine study, while others were simply assigned to cognitive-behavioral treatment subsequently. Initial treatment effects, again showing large effect sizes, rivaled those observed in the original CBT versus fluoxetine study (46) but the benefits deteriorated at 3 months and at 2 years (45). Pretreatment depression was a significant predictor of poor outcome, and the ability to cease HP by the end of behavioral treatment was associated with a greater likelihood of improvement (45). Both of these studies present a risk of being underpowered since they randomized less than 20 individuals per treatment group.

Data suggesting that modulation of glutamatergic pathways might benefit repetitive behavior disorders led to a randomized double-blind placebo-controlled add-on study of *N*-acetyl cysteine (NAC) for TTM in adults (47). NAC showed significant benefits, with 56% responding to drug versus 16% to placebo and clinically significant change in 44% of those on NAC compared to 4% given placebo. There were few ill effects (47). However, when the study was replicated in children (48) there were no differences between drug and placebo, emphasizing that caution should be used when generalizing adult study data to children (48).

Overall, manualized CBT or habit reversal training (HRT) appears to be superior to pharmacologic treatment for TTM (49,50). However, at best the initial gains made in CBT are difficult to maintain and comorbid depression makes them even harder to sustain. At this point there are no specific indicators to suggest which patients will be more likely to respond to CBT/HRT or medication and there are no augmentation strategies that have been studied with sufficient rigor to permit one to recommend them.

Many more questions remain to be answered before we will understand the genetics, neurobiology, course, and treatment of TTM. Although the last decade has seen very significant gains, particularly in understanding the cognitive underpinnings of TTM, it is likely that the larger majority of children with TTM remain to be identified and offered treatment. Clearly without treatment the majority of patients with TTM have very severe impairment in function (49,51). Some individuals develop severe gastrointestinal complications from trichobezoars (52–54). Treatment can improve TTM but there is a gap to be closed on how to sustain those gains. Fifty to 66% of those who receive CBT find their symptoms improve, but of those for whom treatment was successful, only about 50% maintained those gains over 2 years, and the majority required ongoing treatment for many years.

EXCORIATION DISORDER

While the data on TTM are scanty, those on ED, particularly with children and youth,

are more meager yet. Thus, assertions about the prevalence, pathophysiology, treatment, and course of this disorder in children are almost entirely the product of downward extrapolations of adult studies and require confirmation by pediatric-focused research.

The only community-based prevalence study of pathologic skin picking, though flawed, gives a general population estimate of 5% (55) which is close to the 4% rate reported in university students (56,57). Limitations in ascertainment and diagnostic measurement affect the reliability of all of these reports. A community-based (nonclinical) twin study reported a life-time prevalence of 1.2% (58).

The sole genetic study of ED relative to other OCRDs (3) used factor analysis in an adult cohort to explore the relationships among all the conditions in the DSM-5 OCRD chapter. The data suggest a general factor of moderate heritability for all the OCRDs, and an additional factor of moderate heritability for TTM and ED. There were no factors that differentiated genetic risk for TTM from ED, or were unique to ED (3). This is further supported by the twin study, above (58), which found 40% of the variance in the sample could be explained by genetic factors.

So far, there appears to be no unique pathophysiologic features that separate ED from TTM. Like those with TTM (30), individuals with ED show impairments in inhibitory control (59,60), which suggests impairments in the circuit linking the inferior frontal gyrus and anterior cingulate cortex. One neuroimaging study, using DTI, showed that, compared to HVs, those with ED displayed diminished connectivity between cingulate cortex and other regions (61). Of note, the same research consortium reported a similar finding using DTI in those with TTM (36). An fMRI study of females comparing those with ED to those with TTM and to HVs (62) reported greater volumes in the accumbens and thinner cortex in the inferior frontal gyrus and orbitofrontal regions, and thicker cortex in the cuneus bilaterally in the ED cohort; there were no differences in these regions between those with TTM and HVs. The investigators noted the relevance of the involvement of these frontostriatal regions in stimulus-response habit formation.

There are no pediatric treatment data available. In adults, two double-blind, placebo-controlled trials (DBPCT) using SSRIs, one with fluoxetine (63) and the other with citalopram (64), offered mixed results. The fluoxetine study showed benefits on only one of the three primary outcome measures, and in the citalopram study there was no improvement on the primary outcome measure. A DBRCT of lamotrigine showed no difference between drug and placebo (65). A DBPCT of NAC (66) for ED reported statistically significant reductions in severity although the study is marred by a 30% drop out rate among those in the placebo arm, no difference on self-reported changes in picking, and a *clinically* dubious difference of just 0.5 on the CGI-severity scale at 12 weeks. Response rates were 47% in the NAC group compared to 19% of *completers* in placebo (66).

There is only one randomized controlled study of CBT for ED (67); all

participants were college students. Participants were randomly assigned to either four sessions of CBT or a waitlist group, a design with significant limitations. There were significant differences in the primary measures and positive effects were sustained at a 2-month follow-up.

Needless to say, a great deal remains to be learned about ED, particularly in pediatric populations. Nevertheless, growing awareness among clinicians and investigators opens the way to improving our understanding of its course, pathophysiology, assessment, and treatment.

5.6 TIC AND MOTOR DISORDERS

CHAPTER 5.6 ■ TIC DISORDERS

MICHAEL H. BLOCH AND JAMES F. LECKMAN

Tic disorders are transient or chronic conditions associated with difficulties in self-esteem, family life, social acceptance, or school or job performance that are directly related to the presence of motor and/or phonic tics. Tic disorders have been noted since antiquity. The first identified case of Tourette syndrome (TS) in historical literature was recounted in *Malleus Maleficarum* (*The Witches' Hammer*), a 1482 treatise on recognizing and curing demonic possession. Sprenger and Kraemer, the authors of *Malleus Maleficarum,* provide a detailed description of a young priest with motor and vocal tics, who is saved from a fiery death at the stake only by successful treatment with exorcism (1). In later French historical archives, there is a chilling account of one Prince de Conde, a 17th century French nobleman in the court of Louis XIV, who resorted to stuffing objects in his mouth to prevent an involuntary bark when in the presence of his royal highness (2).

Although reported since antiquity, recognition of TS as a distinct neuropsychiatric syndrome, and systematic study of individuals with tic disorders, began only with the reports of French neurologists Itard (1825) and Gilles de la Tourette (1885) in the 19th century. Gilles de la Tourette, in his classic study of 1885, described nine cases characterized by motor "incoordinations" or tics, "inarticulate shouts accompanied by articulated words with echolalia and coprolalia" (3). In addition to identifying the cardinal features of severe tic disorders, his report noted an association between tic disorders and obsessive-compulsive (OC) symptoms, as well as the hereditary nature of the syndrome in some families.

Since the case series presented by Gilles de la Tourette, we have learned that TS typically has a much more benign course than initially suggested in his account. We have also developed some effective pharmacologic, psychological, and now, even surgical, treatments for individuals with TS. With increasing longitudinal assessment of children with tic disorders we have learned that many present or develop a broad array of behavioral difficulties, including disinhibited speech or conduct, impulsivity, distractibility, motoric hyperactivity, and OC symptoms (4). In this chapter, a presentation of the phenomenology and classification of tic disorders precedes a review of the epidemiology, clinical course, neurobiologic substrates, assessment and management of tic disorders, and their associated comorbidities.

DEFINITION

Tics are sudden, repetitive movements, gestures, or phonic productions that typically mimic some aspect of normal behavior. Usually of brief duration, individual tics rarely last more than a second. Many tics tend to occur in bouts, with brief inter-tic

intervals of less than 1 second (5). Individual tics can occur singly or together in an orchestrated pattern. They vary in their intensity or forcefulness. Motor tics, which can be viewed as disinhibited fragments of normal movement, can vary from simple, abrupt movements such as eye blinking, nose twitching, head or arm jerks, or shoulder shrugs to more complex movements that appear to have a purpose, such as facial or hand gestures or sustained looks. These two phenotypic extremes of motor tics are classified as simple and complex motor tics, respectively. Similarly, phonic tics can be classified into simple and complex categories. Simple vocal tics are sudden, meaningless sounds such as throat clearing, coughing, sniffing, spitting, or grunting. Complex phonic tics are more protracted, meaningful utterances, which vary from prolonged throat clearing to syllables, words or phrases, to even more complex behaviors such as repeating one's own words (palilalia) or those of others (echolalia) and, in rare cases, the utterance of obscenities (coprolalia) (6). Clinicians typically characterize tics by their anatomical location, number, frequency, duration, forcefulness, and complexity as outlined above. Each of these elements has been incorporated into clinician rating scales that have proven to be useful in monitoring tic severity (7).

Many individuals with tics, especially those above the age of 10, are aware of premonitory urges that may either be experienced as a focal perception in a particular body region where the tic is about to occur (like an itch or a tickling *sensation*) or as a mental awareness (8,9). A majority of patients also report a fleeting sense of relief after a bout of tics has occurred, and most individuals are able to suppress their tics for short intervals of time (9,10).

DIAGNOSTIC CLASSIFICATION

The currently accepted diagnostic criteria for TS as defined in the International Classification of Disease (ICD)-10 include: (1) presence of multiple motor tics, (2) presence of one or more vocal tics, (3) onset before age 18, (4) tics that may appear many times a day, either everyday or intermittently, (5) presence of tics for a period longer than 1 year, (6) change in anatomic location and character of tics over time, and (7) occurrence of tics not attributable to CNS disease (Huntington disease or postviral encephalopathies) or psychoactive medication or substance usage. Table 5.6.1 depicts the current diagnostic criteria for tic disorders in ICD-10. Diagnostic criteria for tic disorders between ICD-10 and *Diagnostic and Statistical Manual of Mental Disorders Text-Revision (DSM-IV-TR)* are nearly identical.

Tics that appear in childhood are often ephemeral. When a patient exhibits motor and/or vocal tics for less than a year, a diagnosis of a transient tic disorder is made according to DSM-IV-TR and ICD-10, regardless of tic frequency or severity. In DSM-5, children are diagnosed with a transient tic disorder if and only if their tics have subsided within a year's time. A new category of Provisional Tic Disorder

(rather than transient tic disorder) was established for children who are currently having tics but have not had them for a full year. The additional Provisional Tic Disorder category was introduced in DSM-5 because of the recognition that some of these children may go on to develop TS (e.g., their tic disorder is in fact not transient). If either motor or phonic tics (but not both) are present for a year or more, then a diagnosis of chronic motor or phonic tic disorder, respectively, can be made, according to DSM-5 or ICD-10. Chronic tics are viewed by experts as a milder phenotypic expression of TS, while transient tic disorders are generally viewed as a separate entity (4).

TABLE 5.6.1

ICD-10 TIC DISORDER CLASSIFICATION

Diagnostic criteria for F95.2 Combined vocal and multiple motor tic disorder (de la Tourette syndrome)

A. Multiple motor tics and one or more vocal tics have been present at some time during the disorder, but not necessarily concurrently.
B. The frequency of tics must be many times a day, nearly every day, for more than 1 year, with no period of remission during that year lasting longer than 2 months.
C. Onset is before the age of 18 years.

Diagnostic criteria for F95.1 Chronic motor or vocal tic disorder

A. Motor or vocal tics, but not both, occur many times per day, on most days, over a period of at least 12 months.
B. No period of remission during that year lasts longer than 2 months.
C. There is no history of Tourette syndrome, and the disorder is not the result of physical conditions or side effects of medication.
D. Onset is before the age of 18 years.

Diagnostic criteria for F95.0 Transient tic disorder

A. Single or multiple motor vocal tic(s) or both occur many times a day, on most days, over a period of at least 4 weeks.
B. Duration of the disorder is 12 months or less.
C. There is no history of Tourette syndrome, and the disorder is not the result of physical conditions or side effects of medications.
D. Onset is before the age of 18 years.

From the World Health Organization used in Skin Diseases: *ICD-10 Classification of Mental and Behavioural Disorders: Diagnostic Criteria for Research*. Albany, CH, 1993.

CLINICAL COURSE OF TS

The onset of TS is usually characterized by the appearance of simple, transient motor tics that affect the face (typically eye blinking) around the age of 5 to 7 (11). Over time these simple motor tics generally progress in a rostrocaudal direction affecting other areas of the face, followed by the head, neck, arms and last and less frequently, the lower extremities (12). Phonic tics usually appear several years after the onset of motor tic symptoms, at 8 to 15 years of age. Phonic tics seldom appear in isolation without the prior onset of motor tics—fewer than 5% of all patients with tic

disorders have isolated phonic tic disorder, whereas the vast majority of children afflicted with tic disorders have isolated motor symptomatology (10). Tic complexity, also, generally evolves with age. During the first years of TS onset there is a steady unfolding of symptoms with single, rapid motor tics evolving into stereotyped, complex movements and nonsense sounds developing into elaborate words and phrases. The character of these complex phonations and movements are highly unique to the individual. Due to the rapid progression of symptoms during childhood, the vast majority of TS cases are diagnosed by age 11 (10).

Typically, as they grow older, children with TS gain an increasing ability to recognize when tics will ultimately strike and gain control over them. The first transient motor tics TS patients experience in the latency years are usually sudden, involuntary, unconscious movements. Often the afflicted individual is only made aware of the presence of these movements through the reactions of others around him. By the age of 10 or 11, however, many children report premonitory urges: feelings of tightness, tension, or itching that are accompanied by a mounting sense of discomfort or anxiety that can be relieved only by the performance of a tic (9). These premonitory urges are similar to the sensation preceding a sneeze or an itch. Premonitory urges cause many TS patients to suffer from an endless cycle of rising tension and tic performance because the relief provided by tic performance is ephemeral. Thus, soon after tic performance the tension of the premonitory urge again rises to a crescendo (13).

With increasing awareness of premonitory urges, TS patients begin to exhibit a variable degree of voluntary control over tic performance. Ninety-two percent of TS subjects in one study reported that the tics they exhibited were either partially or totally voluntary (9). However, this voluntary control should be likened to that governing control of eye blinking. Eye blinking and tics can both be inhibited voluntarily, but only for a limited period of time and only with mounting discomfort. Thus, some adult TS patients are able to demonstrate nearly complete control over the situation when expression of their tics will occur. However, when complete or near complete control of tics is present, resistance to the mounting tension of premonitory urges can produce mental and physical exhaustion even more impairing and distracting than the tics themselves (12). However, little evidence exists from experimental studies that the active suppression of tics leads to any noticeable effect on future tic frequency and severity (e.g., there is little evidence for any rebound phenomenon due to active tic suppression) (14,15).

The severity of tics in TS waxes and wanes throughout the course of the disorder. The tics of TS and other tic disorders are highly variable from minute to minute, hour to hour, day to day, week to week, month to month, and even year to year (5). Tic episodes occur in bouts, which in turn also tend to cluster. Tic symptoms, however, can be exacerbated by stress, fatigue, extremes of temperature and external stimuli (in echolalia tics) (16). Intentional movements attenuate tic occurrence over the affected

area and intense involvement and concentration in activities tends to dissipate tic symptoms. The power of this effect in many patients with TS is illustrated beautifully in Oliver Sacks' short story, *A Surgeon's Life*. As Sacks writes:

> *And, indeed, whenever the stream of attention and interest was interrupted, Bennett's (the surgeon) tics and iterations immediately reasserted themselves—in particular, obsessive touchings of his mustache and glasses. His mustache had constantly to be smoothed and checked for symmetry, his glasses had to be "balanced"—up and down, side to side, diagonally, in and out—with sudden, ticcy touchings of the fingers, until these, too, were exactly "centered." There were also occasional reachings and lungings with his right arm; sudden, compulsive touchings of the windshield with both forefingers ("the touching has to be symmetrical," he commented); sudden repositionings of the knees, or the steering wheel ("I have to have the knees symmetrical in relation to the steering wheel. They have to be exactly centered"); and sudden, highpitched vocalizations, in a voice completely unlike his own, that sounded like "Hi, Patty," "Hi, there," and, on a couple occasions, "Hideous!"*

Sacks keenly observes that Dr. Bennett's tics and tic-related compulsive behavior are noticeably absent in two situations: (1) in the morning when he is conducting preparatory reading for his later surgeries while simultaneously riding an exercise bike and (2) when performing surgery (17).

Tic severity, however, typically dissipates with the onset of adolescence. TS symptoms generally peak in severity between the ages of 8 and 12 (11,18). Reduction in TS severity generally ends by the early 20s. Although a small minority of TS patients do experience catastrophic outcomes in adulthood, on the whole, individuals rarely experience either a sustained worsening or improvement of their symptoms after the third decade of life. One-half to two-thirds of individuals with TS experience a marked reduction of symptoms by their late teens and early 20s, with one-third to one-half becoming virtually asymptomatic in adulthood (11,19). Figure 5.6.1 diagrams the general course of tic severity of TS patients through the first two decades of their illness (11,18).

PREVALENCE

Transient tic behaviors are commonplace among children. Studies have estimated that 4% to 24% of school-age children experience tics (20–23). The upper end of this estimate was based on a study by Snider et al. (21) that assessed a community sample of 553 children aged 5 to 12 years in a suburban elementary school (21). Assessment was obtained by direct observations by trained observers on each child over multiple occasions over an 8-month period. Snider et al. estimated that 18% of the children (*n*

= 101) experienced a single tic or transient tics. A much smaller portion (n = 34), 6%, had multiple or persistent tics. A similar study by Khalifa and von Knorring examined the prevalence of tic disorders in an epidemiologic sample of 4,479 Swedish children ages 7 to 15 using a three-stage evaluation procedure including screening, parental interview, and clinical assessment. This study estimated the prevalence of chronic motor tics at 0.7% and transient tics at 4.5% in this sample (22). The difference in prevalence measurements of transient and persistent motor tic disorders reported in these studies is likely due to their different ascertainment methods (parent interview vs. direct observation). Nonetheless, the relative commonness of transient tics in the school-age population is evident in both these studies and the difference in prevalence between transient and multiple tic disorders is relatively conserved across studies.
FIGURE 5.6.1. Plot of mean tic severity, ages 2 to 18 years. The *solid line* connecting the small *circles* plots the means of the annual rating of relative tic severity scores (ARRTS) recorded by the parents. The *dashed line* represents a mathematical model designed best to fit the clinical data. Two inflection points are evident that correspond to the age of tic onset and the age at worst-ever tic severity, respectively. (Adapted from Leckman JF, Zhang H, Vitale A, et al.: Course of tic severity in Tourette syndrome: the first two decades. *Pediatrics* 102(1 Pt 1):14–19,

1998.)

Although boys are more commonly affected with tic behaviors than girls, the male–female ratio in most community surveys is less than 2 to 1. For example, in the Isle of Wight study of 10 to 11 year olds, approximately 6% of boys and 3% of girls were reported by their parents to have "twitches, mannerisms, tics of face or body" (20). Similar estimates have been reported from Quebec and from North Carolina (24,25).

There exists drastic variation in estimates of prevalence of TS in the published medical literature. Once thought to be rare, current estimates vary 100-fold, from 2.9 per 10,000 to 299 per 10,000 (26,27). There are three main reasons for this variation in the measurement of the estimation of TS prevalence: (1) The prevalence and severity of tic disorders vary drastically as a function of age (with highest prevalence and greatest severity taking place late in the first decade and early in the second decade of life, and decreasing roughly with the onset of puberty), (2) assessment method of individual studies has varied (patient registries, parent interview, direct observation vs. clinically ascertained cases), and (3) the diagnostic criteria of TS has changed with time—specifically, whether the diagnosis of TS requires an impairment criteria. DSM-III included a requirement that tic symptoms need to "cause marked distress of significant impairment in social, occupational or other important areas of functioning" in order to qualify as TS. By contrast, the impairment criteria were removed in DSM-IV-TR and ICD-10. Estimates of TS prevalence since 1990 among school-age children have estimated a prevalence somewhere between 10 and 100 per 10,000 (22,28–32). Studies incorporating the older DSM-III definition of TS have estimated the prevalence of TS around the lower end of this range, while studies relying on the newer DSM-IV definition of TS not incorporating an impairment criteria have estimated TS prevalence toward its higher end. Estimates of older teenagers and adults with TS are considerably lower, at approximately 4.5 per 10,000 and this result is not surprising since many cases of TS improve drastically or remit completely during the course of adolescence (33).

COEXISTING CONDITIONS

Tics, which are the most prominent feature of TS, are often neither the first nor the most impairing psychological disturbance endured by patients. It has become apparent that children with TS have higher rates of obsessive-compulsive disorder (OCD), attention-deficit hyperactivity disorder (ADHD), and disinhibited speech and behavior compared to individuals in the general population. In one study, 65% of TS patients in late adolescence regarded their behavioral problems (including ADHD and OCD) and learning difficulties to have had an equal or greater impact on their life function than did the tics themselves (34). In the natural course of comorbid

psychiatric illness in TS, ADHD symptoms, when they occur, typically precede the onset of tic symptoms by a couple of years, whereas OC symptoms typically present around the ages of 12 to 13 after tics have reached their peak severity (11,18) (Figure 5.6.2).

Attention-Deficit Hyperactivity Disorder

Clinical and epidemiologic studies sharply differ on rates of ADHD seen among individuals with TS (35). Clinical studies vary according to setting and established referral patterns, but it is not uncommon to see reports of 50% or more of referred children with TS diagnosed with comorbid ADHD. In contrast, epidemiologic studies typically indicate a much lower rate of comorbidity (33). Although the etiologic relationship between TS and ADHD is in dispute, it is clear that those individuals with both TS and ADHD are at a much greater risk for a variety of untoward outcomes (36). Uninformed peers frequently tease individuals with TS and ADHD. They are often regarded as less likeable, more aggressive, and more withdrawn than their classmates (37). These social difficulties are amplified in a child with TS who also has ADHD (38). In such cases, their level of social skill is often several years behind their peers (39).

Negative appraisal by peers in childhood is a strong predictor of global indices of psychopathology (40). This appears to be particularly true for children with TS and ADHD. Children with TS and comorbid ADHD are at much greater risk for disruptive behavior disorders and functional impairment from psychiatric illness than children with TS alone (41). Longitudinal studies confirm that these individuals are at high risk for anxiety and mood disorders, oppositional defiant disorder, and conduct disorder (36,42). Much of this negative impact appears to be due to the ADHD, as children who only have TS tend to fare better (36,41,43). Surprisingly, levels of tic severity are less predictive of peer acceptance than is the presence of ADHD (38). Furthermore, the rates of subsequent psychiatric morbidity seen in TS plus ADHD subjects are nearly identical to those seen in prior cross-sectional and longitudinal studies of ADHD subjects who do not have tics (44,45).
FIGURE 5.6.2. Age at which tics and coexisting disorders affect patients with TS. Width of bars shows schematically the amount the disorder affects a patient at a particular age. (Adapted from Leckman JF: Tourette's syndrome. *Lancet* 360(9345):1577–1586, 2002.)

Obsessive-Compulsive Symptoms

Clinical and epidemiologic studies indicate that more than 40% of individuals with TS experience recurrent OC symptoms (18,46,47). Genetic, neurobiologic, and treatment response studies suggest that there may be qualitative differences between tic-related forms of OCD and cases of OCD in which there is no personal or family history of tics. Tic-related OCD tends to have an earlier age of onset, prior to the ages of 12 to 13, compared to non–tic-related OCD, which usually appears during late adolescence or early adulthood. Patients with OCD and comorbid tics have a significantly higher rate of intrusive violent or aggressive thoughts and images; sexual and religious preoccupations; concerns with symmetry and exactness; hoarding and counting rituals; and touching and tapping compulsions compared to patients with non-tic OCD, who often suffer primarily from contamination worries and cleaning compulsions (46,48). Compulsions designed to eliminate a perceptually tinged mental feeling of unease, coined in the literature as "Just Right" perceptions, are particularly typical of patients with OCD and comorbid tics (47). In addition to global rating scales for OCD, there exist both clinician-rated and self-report instruments to assess the dimensional nature of OCD symptoms. The Dimensional Yale–Brown Obsessive-Compulsive Scale (DY–BOCS), was a clinician-rated and self-report instrument designed to measure the presence and severity of OCD symptoms within six thematically related dimensions and should aid in further

discriminating the OCD experienced by patients with TS compared to those with comorbid tics (49,50). Also the Dimensional Obsessive-Compulsive Scale (DOCS) was designed to measure symptom severity in the four most consistently derived symptom dimensions in OCD (51,52). In addition, tic-related OCD is significantly less responsive to pharmacologic therapy with SRIs than non–tic-related OCD and appears to be more responsive to augmentation with antipsychotic agents (53–56).

In a previous prospective longitudinal study the presence of tics in childhood and early adolescence predicted the future development of OCD (32). Similarly, in a follow-up study of adult outcomes in children with TS, 41% of TS patients experienced at least moderate OC symptoms in adulthood, with these symptoms reaching their worst-ever severity between the ages of 12 and 13 years, an average of 2 years later than tics (18). Also, OC symptoms, when present in children with TS, appear more likely to persist into adulthood than the tics themselves (18). Higher intelligence may also herald a higher risk of developing more severe OCD symptoms in adulthood (18).

ETIOLOGY

Genetic Factors

TS and other closely related disorders clearly have a strong genetic component. The overall risk of an offspring of a parent with TS developing TS is approximately 10% to 15%; the risk of their offspring developing a tic disorder (20% to 29%) or OCD (12% to 32%) is slightly higher (57–60). The risk of developing tic disorders in male offspring is higher, while the risk of developing OCD is less. Twin and family studies provide evidence that genetic factors are involved in the vertical transmission within families of a vulnerability to TS and related disorders (61). The concordance rate for TS among monozygotic twin pairs is greater than 50%, while the concordance of dizygotic twin pairs is about 10% (62,63). If co-twins with chronic motor tic disorder are included, these concordance figures increase to 77% for monozygotic and 30% for dizygotic twin pairs. Differences in the concordance of monozygotic and dizygotic twin pairs indicate that genetic factors play an important role in the etiology of TS and related conditions. These figures also suggest that nongenetic factors are critical in determining the nature and severity of the clinical syndrome.

Several studies involving segregation analysis of large multigenerational families have implicated the possible importance of single gene(s) inherited with an autosomal dominant pattern in the pathogenesis of TS (59,61,64). Unfortunately, genetic linkage studies that have screened the entire genome have eliminated the possibility of a single gene being responsible for TS (65). Despite the well-established large hereditary component of TS, establishing any definitive TS genes

has proven difficult. Numerous genome wide–linkage studies in TS failed to produce any consistent results. In a recently completed genome-wide association study (GWAS), no loci achieved genome-wide significance. However, in the largest GWAS in TS involving 1,286 cases and 4,986 controls, a couple of SNPs were strongly implicated (66). The single nucleotide polymorphisms (SNP) rs7868992 on chromosome 9q32 within the gene *COL27A1* ($p = 1.9 \times 10^{-6}$) was strongly associated with a diagnosis of TS (66). This SNP was replicated in a secondary cohort of 211 cases and 285 controls from two Latin American population isolates from Costa Rica and Colombia. *COL27A1* is a fibrillar collagen primarily expressed in cartilage, although it is also expressed in cerebellum development (67). The role of COL27A1 in the development of the nervous system in unknown (68). The SNP rs6539267 on chromosome 12q23 within an intron of *POLR3B* was also strongly associated with TS in the GWAS sample ($p = 7.4 \times 10^{-6}$) (69). *POLR3B* encodes for a subunit of RNA polymerase III (70). Recessive mutations in POLR3B can cause hypomyelinating leukodystrophy. RNA polymerase III–related hypomyelinating leukodystrophy typically present between early childhood to adolescence and are associated with ataxia, motor regression with upper motor neuron signs, and some mild cognitive dysfunction or regression (71).

Recent analysis of genome-wide common variant data from the same TS GWAS study has estimated that 21% of the hereditability in TS is due to inheritance of rare variant alleles (genes with minor allele frequency less than 5%) (72).

Increasingly candidate gene approaches which identify chromosomal anomalies in patients with TS have been successful in helping us better understand the pathophysiology of the disorder. This sib-pair approach is suited for diseases with an unclear mode of inheritance and has been used successfully in studies of other complex disorders such as diabetes mellitus and essential hypertension. Abelson et al. (73) identified and mapped a de novo chromosome 13 inversion in a patient with TS. The gene SLITRK1 was identified as a brain-expressed candidate gene mapping approximately 350 kilobases from the 13q31 breakpoint (73). Mutation screening of 174 patients with TS was undertaken, with the resulting identification of a truncating frame-shift mutation in a second family affected with TS. In addition, two examples of a rare variant were identified in a highly conserved region of the 3′ untranslated region of the gene corresponding to a brain-expressed micro-RNA–binding domain. None of these anomalies were demonstrated in 3,600 controls. In vitro studies showed that both the frame-shift and the micro-RNA-binding site variant had functional potential and were consistent with a loss-of-function mechanism. Studies of both SLITRK1 and the micro-RNA predicted to bind in the variant-containing 3′ region showed expression in multiple neuroanatomical areas implicated in TS neuropathology, including the cortical plate, striatum, globus pallidus, thalamus, and subthalamic nucleus.

More recently, another strong candidate gene in TS was established through

linkage analysis of a two-generation pedigree in a densely affected family where a father and eight of his children had TS (74). A rare functional mutation was identified in the *HDC* gene, which encodes for L-histidine decarboxylase, the rate limiting step in histamine biosynthesis. The histamine 3 receptor in the brain acts as a presynaptic autoreceptor on histaminergic projection neurons that regulate a variety of neurotransmitters including serotonin and dopamine. HDC knockout mice show decreased brain histamine and increased sensitivity to stereotypies induced by dopamine agonists (75).

Perinatal Factors

The search for nongenetic factors that mediate the expression of a genetic vulnerability to TS and related disorders has also focused on the role of adverse perinatal events. This interest dates from the report of Pasamanick and Kawi, who found that mothers of children with tics were 1.5 times more likely to have experienced a complication during pregnancy than the mothers of children without tics (76). Other investigations have reported that among monozygotic twins discordant for TS, the index twins with TS had lower birth weights than their unaffected co-twins (63,77). Severity of maternal life stress during pregnancy, severe nausea and/or vomiting during the first trimester have also emerged as potential risk factors in the development of tic disorders (78). In 1997, Whitaker and coworkers reported that premature and low birth weight children are at increased risk of developing tic disorders and ADHD. This appears to be especially true of children who had ischemic parenchymal brain lesions. Burd et al. (79) presented the results of a case-control study in which low Apgar scores at 5 minutes and *more* prenatal visits were associated with a higher risk of TS (79). Finally, there exists increasing evidence that maternal smoking during pregnancy may be associated with an increased risk of developing TS (80). Investigations into the effects of perinatal complications into the later development of TS are severely hampered by (1) the possibility that recall bias likely influences results in the retrospective case-control studies addressing this question and (2) multiple hypothesis testing without appropriate statistical correction. However, a recent prospective cohort study from the Danish National Birth Cohort examining over 73,000 singleton pregnancies demonstrated a significant association between maternal smoking during pregnancy and increased risk of development of TS or chronic tic disorders (hazard ratio = 1.66) (81). There was also some evidence of a dosing effect within this study such that children born to heavy smoking mothers during pregnancy had an even further elevated risk of TS or chronic tic disorders (81).

Neuroanatomical Factors

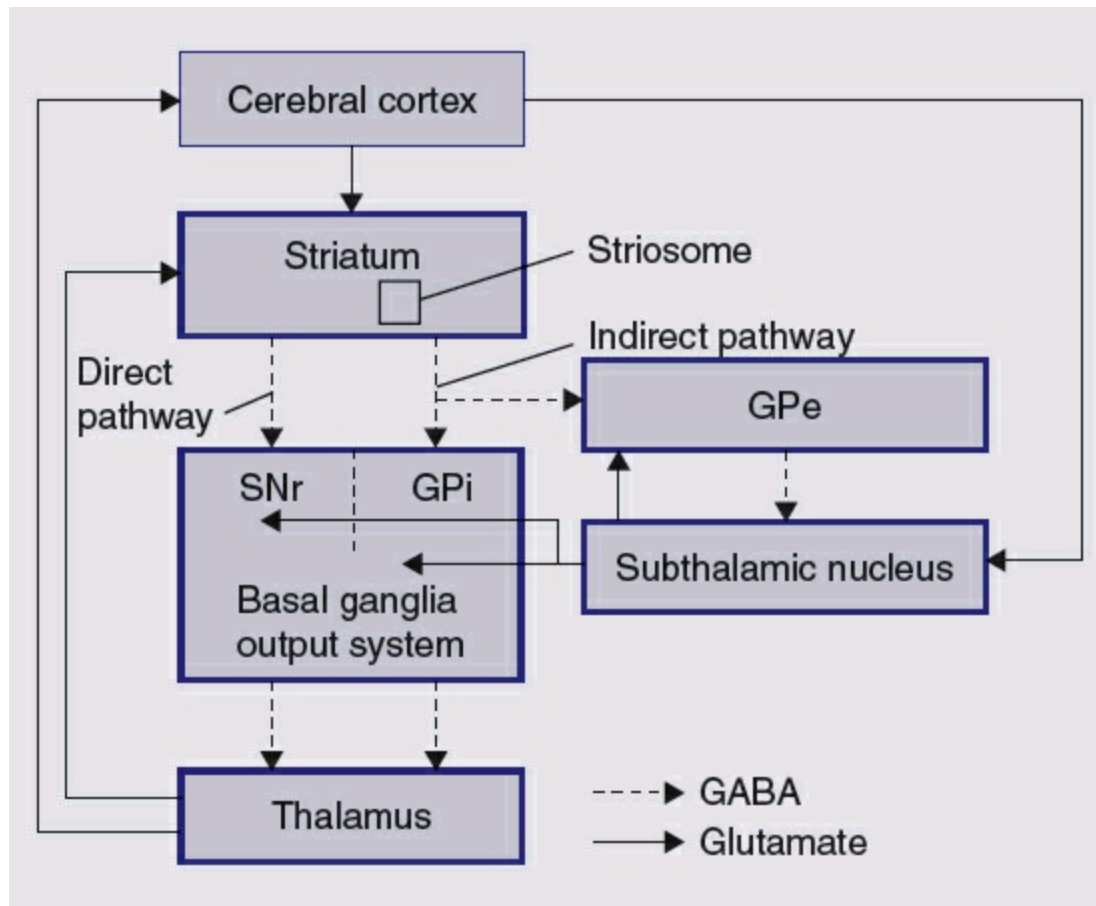
Strong evidence implicates the basal ganglia and corticostriatal thalamocortical (CSTC) abnormalities as central to the pathogenesis of tics. Indirect evidence for the involvement of the basal ganglia in the pathogenesis of TS comes from the association of other movement disorders, such as Huntington disease, hemiballismus, and Parkinson disease, with basal ganglia pathology. Direct evidence supporting CSTC abnormalities in TS comes from neuroimaging, neuropathologic, and neurosurgical studies.


FIGURE 5.6.3. Schematic diagram of the major connections of the basal ganglia. GPe, globus pallidus, pars externa; GPi, globus pallidus, pars interna; SNr, substantia nigra, pars reticulata. (Adapted from Leckman JF: Tourette's syndrome. *Lancet* 360(9345):1577–1586, 2002.)

Dysfunction of frontostriatal circuits is hypothesized to be central to the pathogenesis of TS as well as several other major psychiatric disorders such OCD, TTM, ADHD, and eating disorders (82). Frontostriatal circuits are best known for the execution of planned movements but are also crucial for the performance of many aspects of goal-directed behavior such as elements that drive action such as cognition, emotion, and reward (82). Frontostriatal circuits are multiple, parallel but interacting neuronal circuits which project information from cortical areas to the striatum (caudate, putamen, nucleus accumbens), and back to the cortex via the

thalamus (Figure 5.6.3). Frontostriatal circuits are synaptotopically and hierarchically organized. Abnormalities in two frontostriatal circuits are central to the pathogenesis of TS that initiated from and projecting to (1) premotor and motor cortex and (2) prefrontal cortex (dorsal prefrontal and orbitofrontal cortex) (82).

Premotor cortex is important for the driving, planning, initiation, and execution of voluntary movements. Electrical stimulation of the supplementary motor area can produce (1) synergistic, complex, coordinated movements involving cooperation across multiple joints—movements quite similar to the complex tics seen in TS and sensations involving the "urge" to move—analogous to the premonitory urges experienced by many patients with TS (83). Thus, in TS the frontostriatal circuits projecting from the premotor and motor cortex are hypothesized to be trait deficits of TS that are important in the pathogenesis of tic generation and the premonitory urges of TS. Supporting this hypothesis, functional MRI studies have demonstrated activation of the supplementary motor cortex just prior to tic generation (84,85). Structural neuroimaging examining 25 children with TS and 35 age-matched controls demonstrated thinning of the sensorimotor cortex of children with TS compared to healthy controls (86). Among children with TS, tic severity was associated with degree of thinning of the sensorimotor area (especially dorsal regions) (86). Furthermore, severity of facial tic symptoms was associated with degree of thinning in the ventral sensorimotor cortex (86). The ventral portions of the sensorimotor cortex control the facial, orolingual, and laryngeal musculature.

Prefrontal cortex is important for the planning complex cognitive behaviors, personality expression, decision making, and moderating correct social behavior. The prefrontal cortex's ability to engage in cognitive control through frontostriatal circuits is particularly important for the pathogenesis of TS (87). Cognitive control is the ability to regulate emotional responses and to inhibit temptations or impulses for immediate gratification in the service of waiting for longer-termed delayed rewards (88). Cognitive control of the prefrontal cortex is hypothesized to be particularly important in controlling tic severity and in the pathogenesis of TS. Consistent with this hypothesis, an fMRI study of 22 adults with TS, that activation of the frontal cortex was associated with tic suppression (89). Magnitude of frontal activation during tic suppression was also associated with increased activity in the caudate and decreased activity in the putamen, globus pallidus, and thalamus (89). The magnitude of activity in the caudate (increased) or putamen, globus pallidus, and thalamus (decreased) was significantly associated with severity of tics in the preceding month.

Anatomical neuroimaging studies have consistently demonstrated prefrontal cortex abnormalities compared to healthy controls. The largest neuroimaging on TS to date, involving 155 TS subjects and 131 controls, demonstrated larger dorsolateral prefrontal cortex volumes in children with TS and smaller dorsal prefrontal cortex in adults with active TS (90). Larger dorsal prefrontal volumes in children were associated with decreased tic severity. These data suggest that prefrontal cortex

hypertrophy may represent a compensatory or adaptive process that attenuates tics. Subsequent structural neuroimaging findings have confirmed the association between prefrontal cortex hypertrophy and tic severity—demonstrating a correlation of increased dorsal prefrontal cortex thickness with decreased tic severity in children with TS (86).

The most consistent structural neuroimaging finding in TS is a reduction in caudate nucleus volumes compared to healthy controls. Large cross-sectional neuroimaging studies have demonstrated a small, but significant 5% reduction in the caudate nucleus in TS subjects compared to controls (91). Studies of monozygotic twins discordant for tic severity have demonstrated reduced caudate volumes in the more severely affected twin (92). These reduction in caudate volumes in children with TS have been further associated with the persistence of tic symptoms into adulthood (93). Postmortem neurostereologic studies assessing neuronal density and numbers in five adults with severe, intractable TS and five healthy controls have suggested a possible mechanism for this caudate volume reduction (94,95). TS subjects demonstrated reduced overall number of two types of interneurons in the striatum (94,95). Parvalbumin positive interneurons and cholinergic interneurons were both reduced by over 50% in the caudate and putamen of TS patients (94,95). Furthermore, adult TS patients showed the greatest decrease in cholinergic neurons in the anterior caudate, the area of prefrontal projections (95). Cholinergic neurons were reduced to a lesser extent than in projection areas from the sensorimotor cortex (95). The most posterior limbic projection areas demonstrated similar density of cholinergic interneurons between TS subjects and controls (95). These recent findings strongly implicate prefrontal and sensorimotor projection areas of the basal ganglia in the pathogenesis of TS. These focused loss of interneurons provide a mechanism by which TS patients have impairment of cognitive control or require increasing frontal activation to achieve normal levels of cognitive controls. This loss of interneurons in sensorimotor projection areas also suggests a possible mechanism of tic generation—abnormal firing of striatal projection neurons due to impaired inhibition.

If striatal neurons became overactive in discrete, repeated episodes, the result would be multiple, stereotyped movements—tics (96,97).

Support for this hypothesis of tic generation comes from experiments conducted by Anderson et al. (98), which demonstrated that microstimulation at numerous sites of the putamen produced tic-like stereotyped movements in awake monkeys (98). Furthermore, microstimulation of discrete striatal zones produced characteristic stereotyped movements of individual body parts and, stunningly, even stereotyped movements of multiple body parts reminiscent of complex tics (99).

Human postmortem specimens have fairly consistently demonstrated abnormalities in basal ganglia development or function in the pathogenesis of TS. A postmortem study of three adult patients with severe TS, a markedly higher total neuron number

was found in the globus pallidus pars interna (GPi) of TS. In contrast, a lower neuron number and density was observed in adults with TS in the globus pallidus pars externa and in the caudate nucleus. An increased number and proportion of the GPi neurons were positive for the calcium-binding protein parvalbumin in tissue from TS subjects, whereas lower densities of parvalbumin-positive interneurons were observed in both the caudate and putamen of TS subjects. This loss of parvalbumin-positive fast-spiking interneurons in the striatum has been hypothesized to cause somatotopically arranged clusters of medium-spiny interneurons to become disengaged from their normal high-voltage spindle activity. The result could be a disturbance in discrete CSTC loops through thalamocortical dysrhythmia (a disturbance in the normal rhythmic τ-band activity by the thalamus, in conjunction with ectopic γ-band activity thought to be due to hyperpolarization of thalamic cells), resulting in the premonitory urges and tics characteristic of TS (100). Earlier postmortem studies of TS patients have also reliably demonstrated an association between abnormalities in basal ganglia anatomy, development, and function, and TS (101,102). Abnormalities of the dopaminergic system within the CSTC loops have also been demonstrated in previous postmortem studies. For example, a postmortem study of four adults with intractable TS revealed (1) an increased number of presynaptic dopamine uptake sites in their striatum, (2) increased striatal dopamine levels compared to controls, and (3) similar D2 receptor affinity between TS subjects and controls (101,103).

Neuropharmacologic support for the involvement of CSTC and basal ganglia abnormalities in TS comes from the effectiveness of dopamine-depleting agents (tetrabenazine and alpha-methyl-para-tyrosine) and dopaminergic receptor antagonists (pimozide, haloperidol) in the suppression of tics and from the exacerbation of tics caused by administration of dopamine agonists (L-DOPA) and cocaine (104). Additionally, the application of stimulants directly to specific regions of the basal ganglia of animal models can produce tic-like stereotypic movements (105).

Despite the extensive and diverse neuroimaging studies conducted in TS, it is still a matter of substantial debate whether caudate, thalamic, or cortical dysfunction is primary to the pathogenesis of this disorder. Prospective, longitudinal neuroimaging studies of children with TS are necessary to determine whether the functional and structural abnormalities observed in patients with TS are causes or consequences of the disorder.

Psychological Factors

Tic disorders have long been identified as “stress-sensitive” conditions (106,107). Typically, symptom exacerbations follow in the wake of stressful life events. Children with TS on average experience higher levels of psychosocial stress

compared to matched controls (16). As noted by Shapiro et al. (108), these events need not be adverse in character (108). Clinical experience suggests that in some unfortunate instances a vicious cycle can be initiated in which tic symptoms are misunderstood by the family and teachers, leading to active attempts to suppress the symptoms by punishment and humiliation. These efforts can lead to a further exacerbation of symptoms and further increase in stress in the child's interpersonal environment. Unchecked, this vicious cycle can lead to the most severe manifestations of TS and dysthymia, as well as maladaptive characterologic traits. Although psychological factors are insufficient to cause TS, the intimate association of the content and timing of tic behaviors and dynamically important events in the lives of children make it difficult to overlook their contribution to the intramorbid course of these disorders (36,42). The interaction of TS symptom exacerbation and comorbid depressive symptoms is an area that warrants further investigation. Short-term symptom exacerbation in TS is also influenced by sleeplessness and fatigue, so proper sleep hygiene is also advisable in children with TS.

DIAGNOSTIC ASSESSMENT

Differential Diagnosis

The differential diagnosis of simple motor tics includes a variety of hyperkinetic movements: myoclonus, tremors, chorea, athetosis, dystonias, akathitic movements, paroxysmal dyskinesias, and ballistic movements (109). These movements may be associated with genetic conditions such as Huntington chorea or Wilson disease; structural lesions, as in hemiballismus (associated with lesions to the contralateral subthalamic nucleus); infectious processes as in Sydenham chorea; idiopathic functional instability of neuronal circuits, as in myoclonic epilepsy; and pharmacologic treatments such as acute akathisia and dystonias associated with the use of neuroleptic agents. Differentiation between these conditions and tic disorders is usually accomplished on clinical grounds and is based on the presentation of the disorder and its natural history. For example, although aspects of tics such as their abruptness, their paroxysmal timing, or their suppressible nature may be similar to symptoms seen in other conditions, it is rare for all of these features to be combined in the absence of a *bona fide* tic disorder. Occasionally diagnostic tests are needed to exclude alternative diagnoses.

Complex motor tics can be confused with other complex repetitive behaviors such as stereotypies or compulsive rituals. Differentiation among these behaviors may be difficult, particularly among retarded individuals with limited verbal skills. Stereotypies, as opposed to tics, tend to have an earlier age of onset (2 to 3 as opposed to 6), tend to be bilateral rather than unilateral in nature, the individual movements stay more consistent over time in stereotypies, and stereotypies usually

do not have a waxing and waning course (110). In other settings where these symptoms are closely intertwined, as in individuals with both TS and OCD, efforts to distinguish between complex motor tics and compulsive behaviors may be futile. In cases of a tic disorder, it is unusual to see complex motor tics in the absence of simple tics. Involuntary vocal utterances are uncommon neurologic signs in the absence of a tic disorder. Examples include sniffing and brief sounds in Huntington disease and involuntary moaning in Parkinson disease, particularly as a result of L-dopa toxicity. Complex phonic tics characterized by articulate speech typically can be distinguished from other conditions, including voluntary coprolalia. Because of their rarity in other syndromes, phonic tics can play an important role in differential diagnosis.

Clinical history, family history, observation, and neurologic examination are usually sufficient to establish the diagnosis of a tic disorder. There are no confirmatory diagnostic tests. Neuroimaging studies, EEG-based studies, and laboratory tests are usually noncontributory except in atypical cases.

Assessment

Once the diagnosis has been established, care should be taken to focus on the overall course of an individual's development, not simply on tic symptoms. This may be a particular problem in the case of TS, where the symptoms can be dramatic and there is the temptation to organize all of an individual's behavioral and emotional difficulties under a single, all-encompassing rubric.

The principal goal of an initial assessment is to determine the individual's overall level of adaptive functioning and to identify areas of impairment and distress (4). Close attention to the strengths and weaknesses of the individual and the family is crucial. Relevant dimensions include the presence of comorbid mental, behavioral, developmental, or physical disorders; family history of psychiatric and/or neurologic disease; relationships with family and peers; school and/or occupational performance; and the history of important life events. Medication history is important, particularly if the disorder is longstanding or if medications have been prescribed for physical disorders. It may be necessary to evaluate the adequacy of the prior trials with pharmacologic agents used to treat tic disorders. Table 5.6.2 demonstrates all the components that are important in the initial evaluation of a patient suspected of having TS (111).

Inventories such as the *Yale Child Study Center: TS Obsessive-Compulsive Disorder Symptom Questionnaire* (4) completed by the family prior to their initial consultation can be valuable ancillary tools to gain a long-term perspective of the child's developmental course and the natural history of the tic disorder. In addition, valid and reliable clinical rating instruments that have been developed to inventory and quantify recent tic symptoms, such as the Yale Global Tic Severity Scale, are

particularly useful in judging an individual's current level of tic severity and monitoring changes in tic severity over time (7).

The Yale Global Tic Severity Scale (YGTSS) is a clinician-rated, semi-structured scale that begins with a systematic inventory of tic symptoms that the clinician rates as present or absent over the past week. Current motor and phonic tics are then rated separately according to number, frequency, intensity, complexity, and interference on a 6-point ordinal scale (0 = absent; 1 through 5 for severity) yielding three scores: total motor, total phonic, and total tic score. The scale concludes with an overall impairment rating. The YGTSS has shown excellent inter-rater agreement as well as other desirable psychometric properties (7). Because the YGTSS permits the clinician to incorporate direct observation with historical information, it requires both training with the instrument and clinical experience with tic disorders. At present most investigators consider the YGTSS to be the state of the art with regard to clinician ratings of tic severity.

Direct observational methods include videotaped tic counting procedures (112,113) or in vivo evaluation of tic symptoms (114). These direct observational methods would appear to be the most objective measure of tic severity; however, the frequency of tics varies according to setting and activity. In addition, many individuals with TS can suppress their symptoms for brief periods of time. In practice, videotaped tic counting appears to be most useful for acute research procedures that take place over several hours. Clinically, videotaping can be quite valuable when the diagnosis is in doubt or when tics are not observed in the consultation room.

TREATMENT

Tic disorders are frequently chronic, if not lifelong, conditions. Continuity of care is desirable and should be considered before embarking on a course of treatment. Usual clinical practice focuses initially on the educational and supportive interventions. Pharmacologic treatments are typically held in reserve. Given the waxing and waning course of the disorders, it is likely that whatever is done (or not done) will lead in the short term to some improvement in tic severity. The decision to employ psychoactive medications is usually made after the educational and supportive interventions have been in place for a period of months, and it is clear that the tic symptoms are persistently severe and are themselves a source of impairment in terms of self-esteem, relationships with the family or peers, or the child's ability to perform at school.

TABLE 5.6.2

CLINICAL EVALUATION OF TIC DISORDERS AND CLOSELY RELATED CONDITIONS

1. Tics

Anatomic location and symmetry, number, frequency, intensity, complexity, degree of interference (family and clinician ratings of current and worst-ever severity).

Onset—Age, characteristics (sudden, gradual, associated with stressful life events, infections—particularly recurrent streptococcal infections).

Course—Bout-like occurrence, waxing or waning course, and changing repertoire (most occurring in the eyes, face, head, and shoulders); tic complexity likely to increase with increasing age; momentary suppressibility, reduction during fine motor or vocal tasks that require mental effort, marked diminution during sleep, and usual improvement during the second-half of the second decade of life; intramorbid factors associated with worsening or improvement (stress, fatigue, recent infections); current treatment regimen; history of response to medications (efficacy, side effects, adequacy of trials); history of other interventions.

Associated Perceptual Phenomena and Disinhibited Behavior—Premonitory sensory urges, mental tics, site sensitization, trigger stimuli; socially inappropriate urges or behaviors (calling out in libraries or other quiet public places, urges to do prohibited actions).

Comorbidity—Obsessive-compulsive symptoms; attention-deficit hyperactivity disorder; mood and anxiety disorders.

Impairment—Impact on self-esteem, family function, social acceptance, educational or job performance; risk of physical injury to self or others.

2. Obsessive-Compulsive Symptoms and Behaviors

Range of obsessive worries and thoughts with aggressive, sexual, or religious content, need for symmetry or exactness, a need for things to look, feel or sound "just right," contamination fears, thoughts about saving or hoarding; simple compulsive rituals ("evening-up," ordering behaviors); full-fledged obsessive-compulsive disorder (time-consuming ego-dystonic obsessive thoughts and compulsive rituals that are "resisted" and interfere with normal cognitive function); pathologic doubting; family and clinician ratings of current and worse-ever severity and assessment of obsessive-compulsive symptom dimensions.

Onset—Age, characteristics (associated with recurrent streptococcal infections or the onset of puberty, recent moves, separations, or losses).

Course—Time spent and types of obsessions and compulsions, level of autonomic arousal and anxiety; level of control and resistance; perceived distress if prevented from performing compulsions; role of environmental cues and avoidance behaviors; progression from ego-neutral to ego-dystonic compulsions; changing repertoire of obsessions and compulsions; intramorbid factors associated with worsening or improvement (stress, fatigue, recent infections); current treatment regimen; history of response to cognitive behavioral interventions, medications (efficacy, side effects, adequacy of trials); history of other interventions.

Comorbidity—Depression and other mood and anxiety disorders; obsessive-compulsive personality; schizophrenia; developmental disorders (autism, Prader–Willi syndrome).

Impairment—Impact on self-esteem; subjective distress; pervasive slowness and getting stuck in routine behaviors; impact on family function (level of involvement of the family in the performance of compulsions); effect on social adaptation, educational or job performance; risk of physical injury to self or others.

3. Attention-Deficit Hyperactivity Disorder

Distractibility and impulsive behavior; poor sustained attention, motoric hyperactivity and fidgetiness; associated disruptive behaviors; need for multiple sources of information, especially teachers and other school personnel.

Onset—Age, timing (before or after onset of tic syndrome).

Course—Context dependence: settings where these difficulties are less apparent versus settings of greatest difficulty; history of tutoring and other special educational services; current treatment regimen; history of response to stimulants (efficacy, side effects, adequacy of trials); history of other nonsomatic interventions.

Comorbidity—Oppositional and defiant disorder, conduct disorder, and substance abuse disorders; specific learning disabilities; depression and other mood and anxiety disorders; developmental disorders (fragile X syndrome and other intellectual disability syndromes).

Impairment—Impact on self-esteem; impact on family function especially difficulties with siblings; effect on peer relationships; school underachievement; job performance.

4. Comorbid Developmental, Behavioral, Emotional, Personality, or Substance Abuse Problems

Presence of pervasive developmental disorders (autism, Asperger syndrome, and pervasive development disorder [PDD] not otherwise specified), specific developmental disorders, mood liability and increased irritability, major depression, bipolar disorder, and anxiety disorders (panic disorder, phobias including social and agoraphobia, generalized anxiety disorders), perfectionism and other obsessive-compulsive personality traits, other personality disorders as well as any history of substance abuse.

5. Prenatal and Birth History

Prenatal events (severe nausea and vomiting, maternal emotional stress during pregnancy, history of smoking and alcohol use, other drug and hormonal exposures); birth history (hypoxic episodes, prolonged labor, use of forceps).

6. Developmental, Neurologic, and Pediatric Histories

Developmental delays; exposure to toxins (lead); medication exposures; infectious diseases (streptococcal pharyngitis and other infections such as varicella), rheumatic fever, rheumatic carditis, or Sydenham chorea; head injuries; seizures; asthma; allergies; migraine; disorders of arousal (night terrors, sleep walking).

7. Family and Social Environment, Stress and Adaptive Function, Awareness of Advocacy Organizations

Premorbid history; family environment—stability of family life, coping skills and social supports; relationship of life events (major losses or moves, changes in family circumstances) to onset and exacerbations of symptoms; current adjustment (patient's general knowledge and attitude toward tics, obsessive-compulsive symptoms, and problems with impulsivity and attention, willingness to teach others about symptoms, and the level of understanding and acceptance of the symptoms by close family members); existence of close and lasting friendships; marital status. How aware is the patient and family of the existence of national and local advocacy organizations such as the TS Association (TSA), Obsessive Compulsive Foundation (OCF), and the Children and Adults with Attention Deficit Disorder (CHADD)?

8. School Status

Cognitive level, special talents or gifts, specific learning problems, adequacy of placement, level of understanding and acceptance of the symptoms by school personnel and classmates.

9. Employment Status

Current occupation, job difficulties associated with tic behaviors or related phenomena, adequacy of placement given patient's native abilities, level of understanding and acceptance of the symptoms by employer and coworkers.

10. Family History of Developmental, Autoimmune, Behavioral, and Emotional Disorders

Review of family pedigree with regard to tics, Sydenham chorea, other movement disorders; rheumatic fever; attentional problems and hyperactivity; learning problems; developmental disorders; obsessive-compulsive behaviors; personality disorders; major depression and other mood and anxiety disorders; schizophrenia; alcoholism and other substance abuse disorders.

11. Neuropsychological Assessment

Estimate of cognitive ability, visual motor integration.

12. Physical and Neurologic Evaluations

Health history; evidence of recent physical examinations; throat culture and titers for antistreptolysin O and anti-DNAse B (if requested); presence of soft, nonlocalizing neurologic signs; consider more extensive workup (EEG and structural MRI scan) in atypical cases (negative family history, positive seizure history, history of severe hypoxia, head trauma, marked symptom severity, atypical pattern of response to medication).

Educational and Supportive Interventions

Educational activities are among the most important interventions available to the clinician. They should be undertaken first, not only with patients with severe TS, but with patients with milder presentations. Although the efficacy of these educational and supportive interventions has not been rigorously assessed, they appear to have positive effects by reshaping familial expectations and relationships (115). This is particularly true when the family and others have misconstrued the tic symptoms as being intentionally provocative. Families also find descriptions of the natural history comforting in that the disorders tend not to be relentlessly progressive and usually improve during adulthood. This information often contradicts the impressions gained from the available lay literature on TS that typically focuses on the most extreme cases. Armed with this knowledge, patients and family members and others can begin to understand why waiting before beginning medical treatment makes good sense. If a patient is in the midst of a bad period of tics, it is likely that whether or not a new medication is prescribed, the tics will probably get significantly better in the near future. This insight will also help patients and their families realize why at times in the past their medications have suddenly stopped working. These dialogues can be relieving and can interrupt a vicious cycle of recrimination that leads to further tic exacerbation, and it can help aggravated parents shift the focus from blame to problem solving.

For children, contact with their teachers can be enormously valuable. By educating the educators, clinicians can make significant progress toward securing for the child a positive and supportive environment in the classroom. If possible, teachers need to respond to outbursts of tics with grace and understanding. Repeatedly scolding a child for his tics can be counterproductive. The child may develop a negative attitude toward authority figures and may be reluctant to attend school; classmates may feel freer to tease the child. If tics interfere with a student's ability to receive information in the classroom, it is imperative to find alternative ways to present the material. By helping the student find a way to function even during periods of severe tics, teachers model problem-solving skills that will foster future self-esteem. It is also important for teachers to know that unstructured settings such as the cafeteria, gym, playground, and school bus tend to be very difficult. In these situations, peers who tease or taunt tend to take advantage of the lack of adult supervision. The assignment of a paraprofessional aide to accompany the student can be remarkably beneficial—particularly in situations where there is a history of teasing. Other useful strategies that teachers may consider include: providing short breaks out of the classroom to let the tics out in private, allowing students with severe tics to take tests in private so that a child does not have the pressure to suppress tics during the test period, and being flexible with regard to the scheduling of oral presentations so that the child is not expected to make an oral presentation at a

point when his tics are severe (116). A useful compendium of educational accommodations is available at http://www.tourettesyndrome.net/.

Educated peers are equally important. Many clinicians actively encourage patients, families, and teachers to help educate peers and classmates about TS. It is remarkable what can be tolerated in the classroom and on the playground when teachers and peers simply know what the problem is and learn to disregard it.

Finally, it is important for clinicians to determine the family's awareness and potential interest in advocacy organizations such as the TS Association, Obsessive Compulsive Foundation, and the Children and Adults with Attention Deficit Disorder. In the United States, these organizations have made a positive contribution to the lives of many patients and their families by providing support and information. They can also be a valuable outlet for families, to advance research and raise the general level of awareness among health care professionals, educators, and the public at large. Readers are referred to their respective websites for additional information: Tourette Association of America: www.tourette.org; the International OCD Foundation: www.iocdf.org; and Child and Adults with Attention Deficit: www.chadd.org.

Psychological Interventions

Habit reversal training (HRT) is the first behavioral intervention that has shown promise in reducing tic severity in patients with TS (117). HRT consists of two main focuses: (1) awareness training and (2) competing response practice. Awareness training consists of four components designed to increase an individual's awareness of his or her own tics. These components include: (1) response description, in which an individual learns how to describe tic movements and reenacts them into a mirror; (2) response detection, in which the therapist aids the patient in tic detection by pointing out each tic immediately after it occurs in the session; (3) early warning procedure, in which an individual learns how to identify the earliest signs of tic occurrence; and (4) situational awareness training, in which an analysis is conducted to identify the high-risk situations where tics are most likely to occur. Competing response practice involves teaching individuals to produce an incompatible physical response (isometric contraction of tic-opposing muscles) contingent upon the urge to perform a tic (118).

HRT in its current form, originally developed by Azrin and Nunn (119), and refined by many others over the intervening years, has been demonstrated to significantly reduce tic symptoms in adults with TS, as compared to supportive therapy in randomized controlled clinical trials (120,121). Similar randomized, controlled trials in children with TS have shown similar efficacy. Effect sizes observed for HRT in controlled trials (ES ≈ 0.6 to 0.7) are similar in magnitude to those observed for the most effective pharmacologic treatments for tics (122–124).

Further studies are needed to replicate these current findings at other, less experienced sites with TS. The next challenge is to effectively disseminate this behavioral therapy available only at a few academic institutions to more therapists out in the community. The Tourette Association of America holds several weekend training sessions annually with available off-site supervision in order to help expand the supply of trained therapists.

Pharmacologic Interventions

The decision to begin medication is based on the level of symptoms and the clinical presentation of the individual case. Given the waxing and waning of tic symptoms, it is best to withhold psychotropic medications until the tics, even at their best, are a significant source of impairment. Many cases of TS can be successfully managed without medication. When patients present with coexisting ADHD, OCD, depression, or bipolar illness, it is often better to treat these comorbid conditions first, as successful treatment of these disorders often will diminish tic severity.

A variety of therapeutic agents are now available to treat tics (125). Each medication should be selected on the basis of expected efficacy and potential side effects. Dopamine D2 receptor antagonists remain the most predictably effective tic-suppressing agents in the short term. Documentation of haloperidol's effectiveness in the early 1960s was a landmark in the history of TS, as it called into question the prevailing view that tics were psychogenic in nature (126). The most widely used typical D2 receptor antagonists are haloperidol, pimozide, fluphenazine, and tiapride (not presently available in the United States). Favorable data from double-blind clinical trials are available for haloperidol, pimozide, and tiapride (127–130). The U.S. Food and Drug Administration has approved TS as an indication for haloperidol and pimozide use. Long-term experience has been less favorable, and the "reflexive" use of these agents should be avoided (131,132). Typically, treatment is initiated with a low dose (0.5 mg of haloperidol or 1 mg of pimozide) given before sleep. Further increments (0.5 mg of haloperidol or 1 mg of pimozide) may be added at 7-day intervals if the tic behaviors remain severe. In most instances, 0.5 to 6.0 mg per day of haloperidol or 1.0 to 10.0 mg per day of pimozide administered over a period of 4 to 8 weeks is sufficient to achieve adequate control of tic symptoms. Common potential side effects include tardive dyskinesia, acute dystonic reactions, sedation, depression, school and social phobias, and/or weight gain. In many instances, by starting at low doses and adjusting the dosage upward slowly clinicians can avoid these side effects. The goal should be to use as little of these medications as possible to render the tics "tolerable." Efforts to stop the tics completely often risk overmedication.

Due to the extrapyramidal side effects associated with typical neuroleptics, atypical neuroleptics, such as risperidone, aripiprazole, and ziprasidone have been

used to treat tic symptoms. These agents have potent 5-HT2 blocking effects as well as more modest blocking effects on dopamine D2. Initial favorable double-blind clinical trials have now been reported for risperidone (124), olanzapine (133), and ziprasidone (134). Risperidone and olanzapine use is often associated with weight gain and sedation. Ziprasidone use can be associated with QT prolongation in children so serial monitoring with electrocardiograms may be necessary (135). Recent controlled trials suggest similar efficacy of aripiprazole to other antipsychotic agents (136).

Despite being the most effective pharmacologic agent for the treatment of tics, antipsychotic agents are not generally utilized as a first-line treatment for TS because of their unfavorable side-effect profile. Meta-analysis demonstrated a significant, medium-to-large treatment effect of antipsychotic agents in improving tic symptoms compared to placebo (ES = 0.61 (95% confidence interval [CI]: 0.36 to 0.86), $z = 4.80$, $p = 0.00001$) (137). Further stratified subgroup analysis comparing effect sizes of different antipsychotics (compared to placebo and in head-to-head antipsychotic trials) failed to demonstrate that any particular antipsychotic agent was more effective than any other for the treatment of tic disorders (137). Meta-regression also suggests that there is no association between maximum dose of antipsychotics used in trials and their measured efficacy (137). Therefore, it is advisable to keep antipsychotic doses lower in TS than those typically used for the treatment of psychotic disorders (138).

Clonidine and guanfacine are potent α2-receptor agonists that are thought to reduce central noradrenergic activity. Initial open-label studies of clonidine were favorable, subsequent double-blind clinical trials have had mixed results (138,139). Clinical trials indicate that subjects can expect on average a 25% to 35% reduction in their symptoms over an 8- to 12-week period. Motor tics may show greater improvement than phonic symptoms. The usual starting dose is 0.05 mg on arising. Further 0.05-mg increments at 3- to 4-hour intervals are added weekly until a dosage of 5 mcg per kg is reached, or the total daily dose exceeds 0.25 mg. Although clonidine is clearly less effective than haloperidol and pimozide for immediate tic suppression, it is considerably safer. The principal side effect associated with its use is sedation, which occurs in 10% to 20% of subjects and which usually abates with continued use. Other side effects include dry mouth, transient hypotension, and rare episodes of worsening behavior. Clonidine should be tapered and not withdrawn abruptly, to reduce the likelihood of symptom or blood pressure rebound (140). Guanfacine is another α2-receptor agonist that has been demonstrated in double-blind studies to be effective in the treatment of TS and TS with comorbid ADHD (141). Guanfacine is generally preferred to clonidine because it is less sedating and not associated with rebound hypertension following withdrawal. Guanfacine is generally started at a dose of 0.5 mg at night and then gradually increased by 0.5 mg roughly weekly to TID dosing, with a maximum dose of 4 mg daily (141).

Meta-analysis of randomized, placebo-controlled trials has demonstrated that α2 agonists have a small-to-medium–sized treatment effect in improving tic symptoms compared to placebo (standardized mean difference [SMD] = 0.31 [95% CI: 0.15 to 0.48], $z = 3.64$, $p < 0.001$) (137). Furthermore, comorbid ADHD appeared to have a significant moderating effect on the efficacy of α2 agonists in treating tic symptoms. Trials that only enrolled subjects with comorbid ADHD demonstrated a medium-to-large effect of α2 agonists in reducing tics (SMD = 0.68 [95% CI: 0.36 to 1.01], $z = 4.10$, $p < 0.001$). Trials that excluded subjects with ADHD demonstrated a small, nonsignificant benefit (SMD = 0.15 [95% CI: 0.06 to 0.36], $z = 1.40$, $p = 0.16$) (137). Meta-regression similarly demonstrated a strong positive association between proportion of subjects enrolled in α2 agonist trials and their measured efficacy in treating tic disorders (β = 0.0053 [95% CI: 0.0015 to 0.0091], $z = -2.72$, $p = 0.006$) (137).

Pharmacotherapy of Coexisting ADHD

The stimulants methylphenidate, d-amphetamine, and Adderall are first-line agents for the medical management of ADHD (141). However, the use of stimulants in ADHD associated with a tic disorder is controversial (143). While many patients with both ADHD and a pre-existing tic disorder will do well on stimulants, data from clinical case reports and controlled studies indicate that some children with ADHD will exhibit tics de novo when exposed to a stimulant. Based on this case report level data most psychostimulant medications carry a warning that they are contraindicated in children with tic disorders or having a family history of TS.

Pharmacotherapy of Coexisting OCD

Cognitive behavioral therapies, particularly exposure and response prevention alone or in combination with serotonin reuptake inhibitors (SRIs), are the standard interventions for OCD (144). Unfortunately, many patients with OCD and a coexisting tic disorder respond less well to first-line pharmacologic interventions such as SSRIs (145). Investigators in controlled clinical trials have found that addition of small doses of the neuroleptic haloperidol, or the atypical neuroleptic risperidone, increases the response to SRIs (55,56). OCD patients with comorbid tics seem to be particularly responsive to SRI augmentation with traditional or atypical neuroleptics (55,56). Since OCD patients with comorbid tics seem to respond slightly less well to SSRI monotherapy, it seems to be increasingly important that these children receive access to evidence-based psychotherapy for OCD (e.g., CBT) early in the treatment course especially before being exposed to the significant side-effect burden of antipsychotic medications.

Other Interventions for Tourette Syndrome Typically Reserved for Adult Patients

Botulinum toxin injections are a treatment reserved for adults with severely debilitating tics involving focal muscle groups. Vocal tics (e.g., coprolalia) or motor tics involving the upper face and neck are considered to be the best targets for treatment. These injections should be performed only by an experienced clinician. A single randomized controlled trial of 20 adolescents and adults with TS has demonstrated that botulinum toxin injection was more effective than placebo in reducing tic symptoms (146). However, weakness of the affected muscles is a side effect of treatment which commonly can cause ptosis, dysphagia, hypophonia, and loss of facial expression depending on the muscles injected.

Neurosurgical interventions for TS have been appropriately reserved for adults with intractable tics that severely affect social functioning. Many neurosurgical sites have been targeted for tics in previous lesioning studies—the frontal cortex (147), limbic cortex (148,149), thalamus (150), infrathalamic area (151,152), and cerebellum (153). Increasingly, with the successful use of deep brain stimulation—a relatively reversible, stereotactic technique to treat other movement disorders—DBS has been looked to as the preferred method of neurosurgical treatment for medically intractable tics. The original electrode placement for DBS surgery was placed in the medial part of the thalamus, based on the results of previous lesioning studies. All four patients, who received bilateral medial thalamic DBS surgery, experienced a substantial improvement in tic severity following the procedure (154,155). Two subsequent case reports demonstrated comparable efficacy in bilateral palladial stimulation compared with bilateral medial thalamic stimulation (155). Likewise, the joint activation of both pairs of electrodes did not lead to a further reduction in tic severity (155). DBS has several advantages over previous neurosurgical lesioning procedures in that it lacks many of the permanent complications typically associated with lesioning procedures (the electrodes can be removed), lends access to many surgically inaccessible sites, and allows for bilateral stimulation and thus holds great promise for adult patients with intractable tics (153). However, currently in DBS for tics, neither the appropriate site of electrode placement nor the electrode stimulation parameters have been examined in carefully controlled clinical studies and differ markedly in the few sites willing to engage in this procedure. Therefore DBS is currently not advisable for all but the most severely affected adults with TS (as children with tics will likely get better with time) and even those most severely affected with TS will likely benefit more from the procedure as the protocol is refined over the upcoming years. Any patient considering this intervention should be very discerning regarding the neurosurgical team, especially regarding experience in this area, as no one has much, and should exhaust every possible medical option to treat tics beforehand and conclude that the tics are unbearable despite these

interventions. Any DBS team attempting such surgeries should minimally consist of a neurosurgeon specialized in the stereotactic technique, a neurologist and a psychiatrist trained in movement disorders and their comorbidities, and a specially trained nursing staff (96). The utmost caution is warranted from everyone when engaging in this intervention, especially until the surgical method is improved and this refined method bears the test of more rigorous scientific testing.

FUTURE DIRECTIONS

Recent research efforts have uncovered the first gene, SLTRK1, associated with TS. HRT is the first psychotherapeutic invention proven effective in double-blind studies for TS. DBS, although in its infancy, as applied to TS seems to show some promise in helping the most medically refractory adult patients with TS. Although significant advances in TS treatment have been made, our major challenge over the next few years remains to perfect them and disseminate them to the general public effectively. Despite these advances, our current best available therapies are far from optimum in treating this disorder. Only with an improved understanding of TS will future treatment advances come.

5.7 EATING DISORDERS

CHAPTER 5.7.1 ■ ANOREXIA NERVOSA, BULIMIA NERVOSA, AND BINGE EATING DISORDER

KATHERINE A. HALMI

DEFINITION

Anorexia nervosa (AN) and bulimia nervosa (BN) for many years were regarded as the two major eating disorders. They are complex syndromes with considerable psychiatric and medical comorbidities. After years of obtaining sufficient data and evidence, binge eating disorder (BED) has become a primary diagnosis in the DSM-5. Current abbreviated diagnostic criteria for AN, BN, and BED from DSM-5 (1) are shown in Tables 5.7.1.1, 5.7.1.2, and 5.7.1.3. For those patients who have serious problems with eating behavior but do not fall into the above primary diagnostic categories, the DSM-5 has designated a category of "Other Specified Feeding or Eating Disorder." Most cases of eating disorders have an onset during adolescence.

TABLE 5.7.1.1

DIAGNOSTIC CRITERIA FOR ANOREXIA NERVOSA

A. Restriction of energy intake leading to low body weight in the context of age, sex, developmental trajectory, and physical health. Significant low weight for children and adults is less than minimally expected.
B. Intense fear of gaining weight or becoming fat or persistent behavior that interferes with weight gain.
C. Disturbance in experiencing body weight or shape, undue influence of the latter on self-regard or persistent lack of recognition or the seriousness of low body weight.
Subtype—Restricting or Binge Eating/Purging
Condensed from the American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC, American Psychiatric Association, 2013.

There are three major criteria which define AN. The first criterion is a guideline for defining weight loss, recommending considering age, sex developmental trajectory, and physical health. For children up to the age of 18, pediatric growth charts should be used. Some children may not have weight loss but still weigh less than expected weight because they have failed to make weight gains during a growth in height.

There is no consensus on how weight loss should be calculated, especially with adolescent patients. Some clinicians calculate weight loss below a normal weight for age and height and others figure the amount loss from an original baseline. Body mass index (BMI) is weight in kilograms divided by height in meters squared. This measure is a standard score that somewhat corrects for height and different body build. This index has the advantage of not being subjected to cultural influences. The World Health Organization (WHO) regards a BMI of 18.5 kg/m^2 as the lower limit of

normal body weight for adults. The Center for Disease Control and Prevention (CDC) recommends their BMI for age percentile calculator for children and adolescents and suggests below the 5th percentile as underweight, a BMI between 25 and 30 is considered overweight, and over 30 is labeled obesity.

The second criterion, "intense fear of gaining weight," is present even during emaciated states. Anorectic patients often deny this fear since they are resistant to treatment and thus, their fear of gaining weight must often be inferred by reports of their behavior which reveal rigorous attempts to prevent weight gain such as severe food restriction and exercising.

TABLE 5.7.1.2

DIAGNOSTIC CRITERIA FOR BULIMIA NERVOSA

A. Recurrent episodes of binge eating. B. Recurrent inappropriate behaviors to prevent weight gain; e.g., self-induced vomiting; laxative, diuretic or other medicine misuse; fasting; excessive exercise. C. Binge eating and inappropriate compensatory behaviors occur, on average, once a week for 3 months. D. Self-evaluation is unduly influenced by body shape and weight. E. Above symptoms do not occur exclusively during episodes of anorexia nervosa.
Condensed from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC, American Psychiatric Association, 2013.

TABLE 5.7.1.3

DIAGNOSTIC CRITERIA FOR BINGE EATING DISORDER

A. Recurrent episodes of binge eating B. More episodes of eating: more rapidly than normal, until uncomfortably full, large amounts when not physically hungry, alone due to embarrassment, and feeling disgusted, depressed or guilty afterward C. Marked distress over binge eating D. Binge eating on average at least once a week for 3 months E. Binge eating does not occur with inappropriate compensatory behaviors and does not occur exclusively in the course of anorexia or bulimia nervosa occur exclusively in the course of anorexia or bulimia nervosa
Condensed from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*. 5th ed. Washington, DC, American Psychiatric Association, 2013.

The third criterion, concerning conception of body shape and weight, has evolved into a more complex concept. The significance of body weight and shape are greatly distorted in these individuals. Some feel globally overweight and others realize they are thin but feel certain parts of their body, especially the abdomen and thighs, are too fat. The distorted significance of body weight and shape is related to feelings of insecurity and ineffectiveness. Losing weight and being thin is one area in which these individuals can be effective and in control. The latter undoubtedly influences their denial of the serious medical complications of their malnourished state.

There are two subtypes of AN: the restricting type and the binge–purge type.

Studies have consistently demonstrated that impulsive behaviors including stealing, drug abuse, suicide attempts, self-mutilation, and promiscuity are more prevalent in anorectic binge/purgers compared with anorectic restrictors. Those with anorexia binge–purge type also have a higher prevalence of premorbid obesity, familial obesity, debilitating personality traits, and specific medical complications compared with the anorexia restrictive type (3–5).

The criteria for BN are more arbitrary and less specific than the criteria for AN. In the first criterion for BN in DSM-5, binge eating is defined as eating more food than most people eat in similar circumstances and in a similar period of time. The sense of losing control is a significant subjective aspect that needs to be present. The second criterion, which is the recurrent use of inappropriate compensatory behaviors to avoid weight gain, usually means self-induced vomiting. However, bulimic patients often use cathartics for weight control and have an eating pattern of alternate binges and long fasting periods. The third criterion designed to address chronicity and frequency was changed from twice to once a week for 3 months in DSM-5 in response to clinician-based data that once per week was associated with significant impairment of function. The fourth criterion acknowledges that BN patients are also concerned about their body shape and weight and tend to place excessive estimation of their worth in terms of appearance. The fifth criterion of BN differentiates the latter from the binge–purge subtype of AN.

The first criterion for BED is the same as that for BN, defining binge eating and emphasizing the sense of lack of control. The second criterion provides descriptive criteria surrounding a binge eating episode. Binge eating in BED is associated with significant distress which constitutes the third criterion. The fourth criterion of frequency and chronicity is the same as that for BN, once a week for 3 months. Exclusion of evidence of BN and AN comprise the fifth criterion.

In DSM-5 for the three primary eating disorders specifications are required for partial or full remission and the level of current severity. There are several changes in diagnostic criteria from DSM-IV (2) to DSM-5 for AN, BN, and “not otherwise specified” category. For AN, the most significant change is the deletion of the amenorrhea criterion which did not apply to prepubescent girls, males, or females on contraceptives. Also accurate menstrual history data was often difficult to obtain and comparison between those who were and who were not menstruating revealed no consistent differences. The subtyping of AN into restricting type and binge eating/purging type has changed from current episode to a duration of at least 3 months. Terms implying deliberateness of AN patients; for example, refusal and denial are changed to restriction of energy intake and persistent lack of recognition of the seriousness of current low body weight. Persistent behavior that interferes with weight gain is added to the intense fear of gaining weight since many patients do not admit to the latter. The term “significantly low body weight” remains wisely broad in consideration of age, sex, and developmental trajectory.

For BN, the only major change in DSM-IV criteria is the frequency of binge eating and compensatory behaviors from twice to once/weekly for 3 months.

BED received an official classification in DSM-5 after years of extensive data collection to demonstrate that this diagnosis had sufficient validity and clinical usefulness (24). Although less common in children and adolescents compared to adults, an association was found between binge eating and being overweight.

Eating disorders not otherwise specified (EDNOS) have been replaced with other specified feeding or eating disorder (OSFED). This category includes the three major eating disorders without meeting full criteria but having presence of significant distress or impairment. Also in this category is purging disorder—recurrent purging in the absence of binge eating, and night eating syndrome—recurrent eating after awakening from sleep or excessive eating after the evening meal.

Unspecified feeding or eating disorder is a category for which eating-related symptoms are causing significant distress but criteria are not met for the DSM-5 designated eating disorder diagnoses.

HISTORICAL CONTEXT

Disturbances of eating behavior were described in the Middle Ages. Well-documented case reports of AN are found in the literature describing early Christian saints. Monastery documents record the severe starving behavior and binging episodes of Saint Catherine of Siena, along with the kind of reed she used to induce vomiting and the herbal cathartics she used for purging (3). Another example of this irreversible self-starvation in a fasting female saint is Princes Margaret of Hungary, who lived from 1240 to 1271 (4). She was the daughter of a king and was raised in a Dominican convent where she excelled in all of her studies and in the undesirable chores of the monastery. It is likely that biologic vulnerability factors are similar in those dieting for sainthood during the Middle Ages and those dieting for thinness (attractiveness) in the 20th century. In the 17th century both John Reynolds (5) and Richard Morton (6) described cases of typical AN symptomatology and distinguished them from consumption. In the 19th century Marcé (7), Sir William Gull (8), and Laséque (9) described additional cases of AN and recommended treatment. In the 20th century the first major publication on AN was a book by Bliss and Branch (10) that presented endocrine studies as well as psychological descriptions of the disorder. A decade later, Hilda Bruch (11) further articulated the psychology of AN in her phrase “the relentless pursuit of thinness” and “the paralyzing sense of ineffectiveness, which pervades all thinking and activities.” In 1979, Russell identified BN as a separate entity from AN (12). Subsequently it became apparent that there were young women who had the full syndrome of BN without a history of AN.

After DSM-III-R (13) was published in 1987, clinical evidence was accumulating

for a condition in which binge eating was not followed by compensatory weight reducing behavior. Controlled studies to investigate this condition were strongly encouraged by Robert Spitzer, MD, Chair of the DSM-III-R work group. By 1994, when DSM-IV was published, sufficient studies justified placing BED in the EDNOS section with research criteria. The difficulty in identifying BED as a specific disorder was distinguishing it from BN—nonpurging type and obesity with overeating and defining compensatory behavior. By 2013, BED which qualified as a prime specific diagnosis was presented as such in DSM-5.

EPIDEMIOLOGY, DEMOGRAPHIC CHARACTERISTICS, AND OUTCOME

Most of the studies of incidence and prevalence of eating disorders have been conducted on limited populations such as primary care clinics or medical records with self-report questionnaires. Thus, the true incidence and prevalence of AN, BN, and BED within various countries is not likely truly accurate. The incidence rate, the number of new cases of a disorder in a population over a specific period, is usually expressed for eating disorders as per 100,000 persons per year. Adequate incidence studies are costly and require large samples. Most published data for eating disorders reflect data collection from at least a decade ago using DSM-IV criteria.

Since 1980 until 2000 the incidence of AN in Europe has remained relatively stable. For example, in the United Kingdom new cases in 1988–1993 were 4.2 per 100,000 and in 1994–2000 were 4.7 per 100,000 (14). In the Netherlands, in 1985–1989 there were 7.4 per 100,000 new cases of AN and in 1995–1999 there were 7.7 per 100,000 (15). The incidence of AN in the Netherlands was highest for females aged 15 to 19 and comprised 40% of all cases; 56.4 per 100,000 in 1985 and 109.2 per 100,000 in 1995–1999 (15). Incidence of males was less than 1 per 100,000 in both countries. In the United States, the overall age adjusted incidence in Minnesota for females was 14.6 per 100,000 and 1.8 for males from 1935 to 1989 (16). Among 10- to 19-year-old girls, the incidence rates increased substantially from 1950 to 1984.

Published prevalence studies of eating disorders are more abundant and often conducted on limited populations with varying sensitivity of assessments. Prevalence is usually expressed as point prevalence, occurring at a specific point in time, or lifetime prevalence, proportion of persons that had the disorder at any time in their life.

In the United States, an 8-year prospective study of adolescent girls had a lifetime prevalence by age 20 of AN to be 0.6% with DSM-IV criteria and 2.0% for atypical AN (17). Lifetime prevalence of AN in the United States was assessed in two other large sample studies revealing a lifetime prevalence of 0.3% in 13- to 18-year-old females and males (18) and 0.9% among adult females and 0.3% in males (19). A

population-based study in six European countries (20) had a 0.9% AN lifetime prevalence in females and none in males. More recently over 2,000 children were assessed from age 11 in 2001 to ages 19 to 20 in 2010 in a Dutch community sample. At ages 19 to 20 there was a 1.7% lifetime prevalence of DSM-5 AN in women and 0.1% in men (21).

Mortality rates in AN are high. A 20-year follow-up study had 6.5% deaths with a standardized mortality rate (SMR) of 4.37 for lifetime AN. Duration of illness effected the SMR; 0 to 15 years had a 3.25 SMR and 15 to 30 years had a 6.6 SMR (22). A meta-analysis of 36 studies had an SMR of 5.86 for AN. One in five persons who died committed suicide (23).

A younger age at detection and treatment of AN predicted recovery in a Dutch study. Those 19 years and younger had an odds ratio of recovery of 4.3 compared to those 20 years and older (24). An analysis of 119 studies of outcome found less than half of AN patients had full recovery, 33% improved, and 20% developed a chronic course (25).

BN has few incidence but many prevalence studies. An incidence of 438 per 100,000 person years was found in 15 to 18 Finnish females with BN including those who lacked one criteria for BN (26). In a nation-wide primary care study in the Netherlands the incidence BN rate was 8.6 per 100,000 person years in 1985–1989 and decreased to 6.1 per 100,000 person years in 1995–1999 (15). Likewise, the incidence of BN in the United Kingdom decreased from 12.2 per 100,000 person years in 1993 to 6.6 in 2000. In women aged 10 to 19, the incidence rate of BN remained stable around 40 per 100,000 person years in 1993 and 2000 (14).

Soundy et al. (27) found that the community-based incidence of BN rose sharply from 1980 to 1983 and then remained relatively constant through 1990. The incidence rates of Rochester, MN during that decade were 26.5 per 100,000 per year for females and 0.8 per 100,000 per year for males. The mean age of onset for females is 23 years. Among 15- through 24-year-old adolescent girls and young women, it had become at least twice as common as AN.

Lifetime prevalence of BN in a six European country study was 0.88% in females and 0.12% in males (25). In the United States, a lifetime prevalence of 1.6% for BN was found at age 20 in adolescent females followed for 8 years (17). A point prevalence of 0.6% was reported in 14-year-old Australian adolescents (28). The point prevalence of BN among university women decreased from 4.2% in 1982 to 1.3% in 1992 to 1.7% in 2002 (29). Initially, high rates for BN found in the 1980s were based on DSM-III criteria (30). DSM-IV BN criteria (2) were more restrictive and DSM-5 BN criteria (1) are again less restrictive. Thus increases in BN prevalence may be anticipated with DSM-5 criteria.

There is some evidence that the age of onset of BN is decreasing. Italian BN patients born in 1970–1972 had a mean age onset of 18.5 years compared to 17.1 years in those born between 1979 and 1981 (31). A Dutch high-risk group of BN

changed from 25- to 29-year-old females in 1985–1989 to 15- to 24-year-old females in 1995–1999 (15).

A longitudinal assessment of mortality over 8 to 25 years in 906 BN clinic outpatients produced a crude mortality rate of 3.9% and an SMR of 1.57. The elevated risk for suicide 0.9% was significant and accounted for 23% of the deaths (32). Inconsistent findings are present in outcome studies of BN and vary from recovery in 48% (33) to 70% (34) to 77% (35). Likewise, studies of the effect of various comorbidities on outcome of BN are inconsistent. The most replicable unfavorable outcome factor has been the presence of borderline personality symptoms (36).

BED lifetime prevalence assessed with DSM-IV criteria in the United States found 3.5% women and 2.0% men were effected (19). With DSM-5 criteria applied to this sample BED lifetime, prevalence increased to 3.6% in women and 2.1% in men (37). In a nationally representative sample of US adolescents aged 13 to 18 years the lifetime prevalence of BED was 2.3% in females and 0.8% in males (18). In the six European country study the lifetime prevalence of BED was 1.9% for women and 0.3% for men (20). There were no published incidence studies of BED at the time of this article preparation.

Mortality and outcome studies of BED have been embedded in the EDNOS DSM-IV criteria. However, a German 12-year follow-up of 68 BED inpatients revealed that 2 had died giving a crude mortality rate of 2.9% and a nonsignificant SMR of 2.29 (38). A high comorbidity, 42%, of obesity with BED was present in a large population-based study (19,24).

CLINICAL DESCRIPTION

Two hallmark characteristics of patients with AN are denial of the seriousness of their illness and resistance to treatment, both of which make obtaining an accurate history and producing an effective treatment result a challenge. Anorectic individuals demonstrate their intense fear of gaining weight by their intense preoccupation with thoughts of food and irrational worries about fatness. They frequently look in mirrors to make sure they are thin and incessantly express concern about their appearance. They will take a great deal of time cutting up food into small pieces and rearranging food on their plates in order to eat less. An overwhelming feeling of inadequacy and ineffectiveness is a core symptom of all anorectics. Their success at losing weight is an impressive accomplishment and boosts their self-confidence. Obsessive-compulsive behaviors often develop or become worse as their AN becomes more severe. Obsessions with cleanliness and an increase in cleaning activities and compulsive studying are commonly observed. Perfectionistic traits are common in the restricting type of AN patient.

Many adolescent anorectics have delayed psychosocial development and adults

often have a markedly decreased interest in sex with the onset of AN.

There are important physiologic differences between the two subtypes of anorectic patients. Most of the physiologic and metabolic changes in AN are secondary to the starvation state or to purging behavior. These changes revert to normal with nutritional rehabilitation and the cessation of purging behavior.

In patients with AN who engage in self-induced vomiting or abuse laxatives and diuretics, hypokalemic alkalosis may develop (Table 5.7.1.4). These electrolyte disturbances are associated with physical symptoms of weakness, lethargy, and at times cardiac arrhythmias. The latter condition may result in sudden cardiac arrest, a cause of death in patients who purge. Mild elevation of serum liver enzymes may occur both in the emaciated anorectic phase and during refeeding. This reflects some fatty degeneration of the liver. Elevated serum cholesterol levels tend to occur more frequently in younger patients and return to normal with weight gain. Other common laboratory findings in emaciated AN patients are listed in Table 5.7.1.5. Laboratory findings present with bingeing and purging behavior are listed in Table 5.7.1.6.

Patients with BN should not be below 15% of the normal weight range. If they are, in most circumstances the correct diagnosis will be AN binge–purge (AN-BP) subtype. BN patients can be overweight. The sense of losing control of eating is a significant subjective aspect that occurs during binge eating. Abdominal pain or discomfort, self-induced vomiting, sleep, or social interruption usually terminate the bulimic episode, which is followed by feelings of guilt, depression, or self-disgust. Bulimic patients have a fear of not being able to stop eating voluntarily. Thus, ironically they may fast for long periods of time, lose control because of severe hunger, and then binge eat. Thus, they completely forgo a normal eating pattern and establish a routine of alternate binges and fasts. The food consumed during a binge usually has a high dense caloric content and a texture that facilitates rapid eating. Frequent weight fluctuations occur in BN but without the severity of weight loss present in AN. Most bulimic patients have difficulty feeling satiety at the end of a normal meal. They usually prefer to eat alone and at their homes. About one-fourth to one-third of these patients will have had a previous history of AN.

TABLE 5.7.1.4

COMPLICATIONS OF BINGEING AND PURGING BEHAVIOR

1. Dental enamel erosion and caries
2. Perioral dermatitis
3. Periodontitis
4. Subconjunctival hemorrhage
5. Esophageal or gastric rupture
6. Metabolic alkalosis with hypokalemia
7. Cardiac arrhythmias
8. Cardiomyopathy and cardiac failure secondary to ipecac abuse
9. Renal failure
10. Seizures

TABLE 5.7.1.5

COMMON LABORATORY FINDINGS IN EMACIATED ANOREXIA NERVOSA

1. Hematologic
   Anemia
   Leukopenia with relative lymphocytosis
2. Serum and plasma
   Hypercarotenemia
   Hypoproteinemia
   Hypercholesterolemia
3. Endocrine
   Decreased estrogens
   Decreased testosterone (in males)
   Immature secretion pattern of luteinizing hormone
   Decreased or blunted luteinizing hormone-releasing hormone
   Decreased triiodothyronine
   Increased corticotropin-releasing hormone
   Increased fasting and impaired growth hormone secretion responses
   Blunted diurnal cortisol levels
   Uncoupled vasopressin secretion from osmotic challenge
   Low basal metabolic rate
   Reduced bone density

Majority of BN patients have depressive signs and symptoms. They have problems with interpersonal relationships, self-concept, impulsive behaviors, and also show high levels of anxiety and compulsivity. Alcohol abuse and other drug dependency are not uncommon in this disorder. Bulimics will abuse amphetamines to reduce their appetite and lose weight. As is present in the binge–purge type anorectic patient, BN patients can have severe erosion of the enamel of their teeth, pathologic pulp exposures, loss of integrity of dental arches, diminished masticatory ability, and an obvious unaesthetic appearance of their teeth.

Parotid gland enlargement is associated with elevated serum amylase in bulimics who binge and vomit. Other complications of bingeing and purging behavior are listed in Table 5.7.1.5. Severe abdominal pain in the bulimic patients should alert the physician to a diagnosis of gastric dilatation and a need for nasal gastric suction, x-rays, or surgical consultation.

TABLE 5.7.1.6

COMMON LABORATORY FINDINGS WITH BINGEING AND PURGING BEHAVIOR

Hypokalemia
Hypochloremic alkalosis
Elevated serum amylase
Electrocardiogram—QT- and T-wave changes
Photon absorptiometry—reduced bone density

Cardiac failure may be caused by a cardiomyopathy from ipecac abuse. This is a medical emergency that usually results in death. Symptoms of pericardial pain, dyspnea, and generalized muscle weakness associated with hypotension, tachycardia,

and electrocardiogram abnormalities should alert one to possible ipecac intoxication (39).

BED patients are similar to those with BN in that they engage in binge eating and feel a loss of control over eating. Also in common with many BN patients, those with BED feel disgusted, depressed, or guilty after a binge. However, the difference is those with BED do not engage in behaviors such as vomiting, laxative abuse, or exercise to lose the calories gained in a binge. Shame and embarrassment about their eating behavior makes it difficult for BED persons to seek treatment and be forthcoming about their problem. The majority have functional impairments in work, school, social, or family domains. Comorbid psychiatric disorders such as mood, anxiety, impulse control, or substance use are common (40).

ETIOLOGY AND PATHOGENESIS

The development of AN and BN is best conceptualized within the framework of a multidimensional model, which states that these disorders begin with dieting behavior. Antecedent conditions such as social and cultural influences, family environment, psychological or personality characteristics, and biologic vulnerabilities impact on the dieting behavior to produce the full-blown disorders of AN and BN. As fasting behavior, weight loss, and binge/purge behavior continue, significant psychological and physiologic changes occur. Some of these changes are strong secondary reinforcers that allow the process of fasting, weight loss, and binge/purge behavior to continue.

Secondary psychological reinforcement occurs when the young women initially receive compliments for their weight loss and later realize this is one area of their life in which they can be extremely effective and in control. Binge eating patients soon achieve a relief of anxiety during their binge eating even though that is followed by unpleasant feelings of guilt and depression. The physiologic reinforcements are less precisely defined. For example, with the period of only 8 hours of fasting, there is an increased secretion of corticotrophin-releasing hormone (CRH), which is a potent anorectic agent. This may be effective in assisting some anorectics to continue their decreased calorie intake. Exercising causes a release of norepinephrine and endogenous opioids, which may also reinforce a feeling of exhilaration. Dopamine is released during vomiting and this may reinforce purging behavior. Some chronic BN patients have described receiving a high after self-induced vomiting.

SOCIAL AND CULTURAL INFLUENCES

Data obtained in the 21st compared to the 20th century show epidemiologic and demographic changes have occurred in eating disorders most likely due to social and

cultural influences. Whereas in Western Europe and North America in the past decade the incidence of AN has been relatively stable with BN decreasing in Caucasian women (14,15,29), eating disorders are increasing in minority groups as well as increasing in Asian and Arab countries along with industrialization, urbanization, and globalization (41). There is evidence that eating disorders and disturbed eating behaviors are increasing in China, Singapore, South Korea, Egypt, Pakistan, United Arab Emirates, Oman, Lebanon, Kuwait, Iran, and Jordan (41).

Conceptualization of the emergence of eating disorders has consistently included social and cultural influences. The latter has been investigated within ethnic groups in the United States as well as globally. Most of the recent studies in the United States were conducted on college students with questionnaire surveys rather than structured interviews.

Data from the NIMH Collaborative Psychiatric Epidemiological Studies (CPES) found no significant differences in prevalence for AN and BED in the United States across Latinos, Asians, African Americans, and non-Latino Whites (42,43). BN was more prevalent among Latinos and African Americans than non-Latino Whites (43). Utilization of mental health services was lower in all ethnic minority groups compared to non-Latino Whites (43). Other differences were present among ethnic groups. For African American women, perceived levels of peer attitudes toward weight and shape were positively associated with levels of body dissatisfaction. For white women, body dissatisfaction remained constant across low and high perceived levels of peer attitudes on weight and shape (44). For those presenting for BED treatment, blacks had a higher BMI and binge eating frequency than whites and lower depression than white and Hispanic groups (45). A survey of female college students found black women compared to white, Asian, and Hispanic women had greater self-esteem, were less likely to compare their body to those in the media, and felt less pressure to attain the media set physical appearance (46).

Another study has emphasized a small proportion of Latinos reporting distress with eating disorders seek treatment. Factors contributing to this are lack of health insurance, lack of affordable and accessible treatment services, and beliefs about seeking treatment (47). A study of Mexican American women suggests those who are less acculturated are more satisfied with their bodies (48). A survey of American college students found Arab Americans reported the highest prevalence, 10%, of binge eating (49). Despite some of the ethnic differences in eating disorders found in the United States, it is of interest to note that a prevention program was similarly effective for Asian, African, European, and Hispanic American female college students (50).

The development of eating disorders has also been found to be associated with various social factors. It is possible that the social and economic disadvantages present in non-Caucasian girls may sensitize them toward the culturally dominant body ideals and thus instill a risk factor for developing eating disorders. For

example, a study of AN in Curacao found cases in only mixed ethnicity women who reported that thinness allowed them greater acceptance in the more affluent white community (51).

Feminist theories emphasize that women are indoctrinated into a belief system that overvalues feminine beauty, and in particular thinness. Women cannot achieve satisfactory self-esteem without attaining ideals that are impossible to fulfill. Eating disorders then become the adaptive response to the stress of demands that women conform to an impossible and oppressive social expectation. Some support for this hypothesis comes from a study done in Japan, which suggested eating pathology there may be linked to a conflict between traditional and modernizing roles for women (52).

Peer groups that tout slimness contribute to the risk for the development of eating disorders. In a study of 9- to 11-year-old girls, Wardell and Watters (53) found that greater exposure to older peers in school was associated with increased weight concern, dieting, and thinner size ideals. In another study, sorority women were found to maintain a more rigorous dietary control than nonsorority women (54). Peer groups transmit and reinforce social values that perpetuate risk for body dissatisfaction and eating disorders (55). Higher rates of eating disorders are reported in sport activities in which leanness is valued, such as dance, gymnastics, and among jockeys (56). A study in England showed that girls from a higher social economic status environment reported greater exposure to weight loss and dieting by family and friends and the higher SES girls indicated a greater awareness of ideals of thinness (57).

Several studies have found an adverse effect of the media on body image, eating attitudes, and behaviors. In one study, magazine exposure to thin body images found the resulting body dissatisfaction was mediated by internalization of thin ideals (58). In another study of college women, Low et al. (59) found internalization of the thin ideal was associated with increased eating and weight concerns. An increased desire to emulate unrealistic body standards was found in grade school girls and boys who were exposed to pictures of “ideal men and women” (60). Adolescent girls exposed to commercials depicting thin, attractive models reported feeling more dissatisfied with their bodies and expressed a greater drive for thinness 2 years later in a study by Hargreaves and Tiggeman (61).

STRESSFUL LIFE EVENTS

Childhood trauma which consists of either emotional abuse, physical abuse, sexual abuse, emotional neglect, physical neglect, or any combination of the above has been the most frequently investigated stressful life event related to eating disorders. Most studies of childhood trauma have been conducted with retrospective questionnaires. A meta-analysis of sexual abuse studies found an increased risk of a lifetime

diagnosis of multiple psychiatric disorders including eating disorders (62). One study found childhood physical abuse and childhood sexual abuse contributed independently to increased risk of eating disorders among women (63). However, sexual abuse rarely occurs in isolation since physical and emotional abuse are often present. Another study found that emotional abuse was the only abuse type that consistently related to eating disorder symptoms (64). In this study, emotional dysregulation mediated the effect of emotional abuse on eating disorder symptoms. In girls, negative/depressive affect mediated the relationship between childhood maltreatment and eating disorder psychopathology in a study of adolescent psychiatric inpatients (65).

Additional personality characteristics or traits were found to interact with child sexual abuse and eating disorders. Avoidant personality disorder and child sexual abuse interacted in predicting poor outcome in chronic eating disorder patients (66). Another study found those with eating disorders and childhood abuse had elevations of a dysregulated or impulsive psychopathology (67). Emotional dysregulation explained the relationship between childhood emotional abuse and AN symptom severity in patients from an intensive treatment facility (68).

Binge eating behavior has been especially associated with childhood abuse. Higher rates of the latter were found in AN with binge–purge behavior than AN restricting type (69). Women with BED reported rates of childhood maltreatment much higher than those in community samples (70). Childhood onset in comparison to adult onset of binge eating was associated with higher rates of lifetime BN, greater severity of BN symptoms, and higher rates of abuse (71).

There is some evidence that childhood abuse in genetically susceptible persons may lower modulation of stress reactions and thus increase the likelihood of developing an eating disorder. For example, an association was found between BN and the low function variant of the Bcll polymorphism (low glucocorticoid receptor sensitivity) and prior abuse (72). Another study found genes within the dopamine system (DRD2 and COMT) were interacting with childhood abuse and bulimic behaviors (73). The effect of adverse life events on binge eating was moderated by the 5-HTTLPR serotonin transporter promotor polymorphism (74).

For clinicians it is important to inquire into the full range of childhood traumatic experience including physical abuse, emotional abuse and neglect as well as sexual abuse.

In the premorbid vulnerable individual, normative developmental events such as the onset of puberty, leaving home, beginning school, and the start of new relationships have been precipitating events for the onset of an eating disorder (75). Adverse life events such as the death of a close relative, the breakup of a relationship, or an illness have also been related as precipitant of eating disorder problems.

BIOLOGIC FACTORS

Genetic Factors

A genetic vulnerability may be direct, through the inheritance of genes that are directly associated with the development of AN or BN. An indirect genetic predisposition on the other hand could become manifest with genetic vulnerability under adverse conditions such as inappropriate dieting or emotional stress. These predispositions could be a particular personality type, a tendency to susceptibility to psychiatric instability (especially affective or anxiety disorders), or a neurocircuitry dysfunction.

Behavioral genetics including family, twin, and adoption studies have provided evidence for a genetic influence on a liability to eating disorders (76,77). Family studies found an increased risk of both AN and BN in relatives of AN and BN probands and more BED in first-degree relatives of those with BED. Twin studies comparing identical with fraternal twins have reported heritability estimates ranging from 33% to 84% for AN, 28% to 83% for BN, and 41% to 57% for BED with the remaining variance attributable to unique environmental factors (78,79). Twin studies have also identified possible endophenotypes (measurable markers observable in the affected proband in both well and ill states). For example, puberty and age seem to moderate genetic influence on eating disorder traits (80,81). Adoption studies comparing biologic and adopted female sibling pairs found heritability estimates for disordered eating symptoms ranged from 59% to 82% (82).

Molecular genetic studies have rapidly increased in the past decade. Those involving eating disorders have used either a linkage, case association method, or genome-wide association analysis. In linkage analyses, variation in the paternal and the maternal contribution to the genome of the offspring is used to localize genes that influence a trait. In the association study, cases that display a trait of interest are compared to controls who do not have the trait. Candidate genes are genotyped and the allele and genotype frequencies are compared in cases versus controls. An association study can also be done in an affected individual and both biologic parents. This is called a transmission disequilibrium test (TDT). In the TDT approach, the transmission versus nontransmission of marker alleles to affected offspring is compared.

Linkage analyses identify genomic regions that may harbor risk or protective loci by identifying genetic markers that are coinherited with the eating disorder phenotype. A multisite found significant peak linkage for AN on chromosome 1 and for BN on chromosome 10 (83,84). Genotyping single nucleotide polymorphisms (SNPs) in the peak linkage area on chromosome 1 revealed possible candidate gene variants at the delta opioid receptor (OPRD1) and the serotonin 1 D receptor (HTR1D) (85). These associations were confirmed by an independent study (86).

Genetic case association compares variants that are hypothesized to be involved in the pathophysiology of eating disorders in those with eating disorders and controls. In the past decade many of these analyses conducted resulted in contradictory or nonreplicable findings. These investigations focused on SNPs in genes involved in the regulation of neurotransmitters, serotonin, dopamine, and norepinephrine or neuronal function and growth brain-derived neurotropic factor (BDNF) or the regulation of hormones, leptin, ghrelin, and adrenocorticotropin. The BDNF polymorphism, Met 66 variant was associated with the restricting type of AN and confirmed with both a case control design and a TDT approach (87).

Genome-wide association studies (GWAS) compares over 500,000 loci (SNPs) in each case and control. Extremely conservative significance thresholds are necessary for these multiple comparisons usually requiring sample sizes of more than 5,000 cases to detect significance. One GWAS with 1,033 cases of AN and 3,773 controls was negative for SNPs meeting genome-wide significance (88).

Epigenetics, the study of mechanisms that regulate gene expression independently of DNA sequence, most frequently examine DNA methylation. Methylation changes are usually examined in the blood and if present may not be in other tissues such as the brain. A methylation study of AN women found global DNA hypomethylation and hypermethylation of the DRD2 promotor (89). BN women had hypermethylation of the atrial natriuretic peptide (ANP) gene promotor region and down regulation of ANP in RNA (90). DRD2 is associated with dopamine regulation and ANP inhibits CRH which may have an anxiolytic effect (91).

Genetic studies at this date have had limited success in identifying gene variants associated with eating disorders. However, epigenetic mechanisms have produced gene x environment interactions which future research may discover highly relevant to the development of eating disorders.

Neuroendocrine and Neurocircuitry Factors

Ingestive behavior which is disturbed in eating disorders is controlled and influenced by many biologic factors. In the past two decades biologic investigations have focused on neurotransmitters and peptide hormones.

Under stress, such as severe dieting, vulnerability for destabilization of some of the endocrine and metabolic mechanisms affecting eating behavior may influence the development of a full-blown eating disorder. Most of the neuroendocrine changes in the eating disorders are directly related to dieting behaviors, weight loss, and reduced caloric intake. These changes revert to normal with resumption of normal eating behavior and nutritional rehabilitation. For example, increased CRH secretion occurs in underweight anorectic patients and in normal weight dieting individuals but returns to normal with weight restoration. However, CRH is a potent anorectic hormone and may have a role in maintaining anorectic behaviors and initiating a

relapse.

It is well established that pituitary cells producing luteinizing hormone are understimulated in patients with AN because of hyposecretion of GnRH by the hypothalamus. A dysfunction may be present in the neurotransmitter systems that influence GnRH release and secretion. The considerable difference in patterns of severe dieting and fasting in BN patients probably explains the variability in the function of the hypothalamic–pituitary–ovarian axis as measured in various studies of BN patients. Some anorectic women remain amenorrheic for long periods of time (several years) after weight restoration. Studies have shown these women to be more psychologically disturbed compared to those who have a rapid resumption of menses (92).

Serum levels of leptin, a product of an obesity gene, were shown to correlate significantly with BMI and the amount of adipose tissue in AN patients. Thus, emaciated anorectics have extremely low levels of leptin, which increase as the patients gain weight (93). Baseline serum leptin levels in BN patients compared with controls have shown variable results (94). A compounding factor is that leptin levels decreased during short periods of caloric deficit. It is unlikely that leptin is a causal agent for producing eating disorders. Adiponectin is another adipokine protein that is released from adipose tissue and has an effect of enhancing insulin sensitivity. An inverse correlation between adiponectin and BMI is consistent with the increased adiponectin levels found in AN and variable findings in BN (95).

Ghrelin is a peptide released from endocrine cells in the stomach which acts in the hypothalamus to increase meal size (96). Fasting baseline plasma ghrelin levels were not different in BN patients compared with controls (97). However, the ghrelin response to standardize meals was significantly attenuated in patients with BN compared to controls (98). This suggests an impairment of postingestive satiety in BN with abnormal ghrelin regulation possibly contributing to the binge eating episodes. In AN patients' plasma ghrelin levels are elevated in comparison to healthy controls, and these levels decrease toward normal values as patients regain their weight (99). The relationship of these peptide levels to various clinical symptom patterns needs to be clarified.

More recently, neuroimaging paradigms have provided much information on serotonin and dopamine circuitry in the processing of food, reward, fear, and cognitive stimuli. In studying eating disorders it is important to document state-related factors such as electrolyte and metabolic conditions. The neurotransmitters, serotonin and dopamine, have been conceptualized within anxiety and reward circuitries. Serotonin which is associated with anxiety is also inhibitory to feeding, exploratory and sexual behaviors, all of which are inhibited in AN. Positron emission tomography (PET) studies showed 5HT2A binding was reduced in recovered restricting AN (AN-R) in the insula, cingulate, mesial, temporal, and occipital cortex. In AN-BP recovered women 5HT2A binding was reduced in the

cingulate, parietal, and occipital cortex. In both AN subtypes 5HT2A binding was positively related to harm avoidance, an anxious trait (100). These findings may influence connections between the affected cortical areas and the amygdala and thus produce impairment in cognitive and emotional pathways.

In recovered BN reduced orbital-frontal 5HT2A receptor binding could be related to impulsiveness and emotional dysregulation (100). 5HT1A from two PET studies showed increased activity across frontal, temporal, and parietal cortex areas as well as in the dorsal raphe in recovered AN (101,102). This activity was also positively correlated with harm avoidance. BN persons showed increased 5HT1A receptor binding in the prefrontal, cingulate, and parietal cortical areas, also implicating anxiety features (100). No differences were found in serotonin transporter (5HT-T) availability between AN individuals and controls (100). However a single-photon emission computerized tomography (SPECT) study showed reduced 5HT-T binding in the thalamus and hypothalamus in ill BN persons and varying binding results in different brain areas after recovery (103). 5 HT-T regulates serotonin levels in the synapses. Low serotonin synaptic levels may explain higher dosages of serotonin reuptake inhibitors needed to reduce binge eating.

Food image studies with functional magnetic resonance imaging (fMRI) provoked anxiety and increased activation in the anterior cingulate and medial prefrontal cortex in both ill and recovered AN persons compared to controls, suggesting a possible trait marker for AN (104,105). Similar responses were present in BN persons (105).

Changes in brain dopamine and reward functioning have been demonstrated in AN. PET studies in recovered AN women revealed increased D2/3 receptor availability in the ventral striatum (106). AN women had a greater response in the striatum during fMRI to images of thin bodies compared to controls (107). Recovered AN women had a reduced functional brain response with fMRI to repeated applications of taste in the insula and ventral and dorsal striata (108). Those with AN did not distinguish between win and loss in the ventral striatum in response to monetary reward stimuli (109). These findings may indicate altered brain dopamine reward circuitry in AN. There are few studies of dopamine reward circuitry in BN. One fMRI study found reduced response in the ventral putamen, insula, and prefrontal cortex in BN persons to a dopamine-related reward paradigm (110).

More recently, the technique of diffusion tensor imaging was used to demonstrate larger anteroventral gray and white matter volume in adolescents with AN compared to controls. Also present was lower white matter integrity in posterior frontal and parietal regions. The authors implied this finding may indicate developmental factors such as gray matter pruning and white matter growth could contribute to brain alterations in AN (111). Another study using diffusion imaging processing in adult recovered AN women found white matter integrity was reduced across large frontal regions and in the cerebellum. The authors suggested this abnormality could result in

less efficient information processing and interfere with the neurocircuitry of food–reward processing. These findings may reflect a premorbid trait or a remodeling after an underweight state (112). It is not clear how these findings suggesting impairments in brain neurocircuitry involving anxiety and reward-related brain pathways, especially in the insular and cingulate cortex and basal ganglia, may specifically effect eating behavior.

PSYCHOLOGICAL FACTORS

Psychological factors may be conceptualized as predating the onset of eating disorders, occurring in the acute phase of illness and persisting after recovery. Perfectionism is a psychological feature initially identified with AN. A multisite genetic study found higher perfectionism scores on the Frost Multidimensional Perfection Scale in AN persons compared to healthy persons. In those with AN greater perfectionism was associated with lower body weight, greater eating preoccupations and rituals, and diminished motivation to change (113). Also perfectionism was most severe in those with obsessional compulsive personality disorder (OCPD) or the combination of OCPD and obsessive-compulsive disorder (OCD) (114). Trait anxiety, which is a common feature of AN, predicted a lower likelihood of recovery in a multisite study of 680 AN women (115).

A meta-analysis of the Temperament and Character Inventory (TCI) in 14 studies found persistence and harm avoidance was significantly higher in AN persons compared to BN, BED persons, and controls. Recovered AN persons had significantly lower harm avoidance and higher reward dependence compared to those acutely ill with AN. Novelty seeking was significantly elevated only in those with BN (116). Other studies found BN, compared to controls, to have greater impulsivity and low self-directedness (117). These psychological features may represent enduring temperament traits that contribute to eating disorder pathogenesis.

In a community sample personality features associated with BED included high novelty seeking, higher harm avoidance and low self-directedness (118). The authors suggested two types of BED; an impulsive novelty seeking type and another with harm avoidance and mood dysregulation.

Current research suggests high harm avoidance, low self-directedness, perfectionism, and anxiety traits are risk factors for developing and maintaining an eating disorder.

Negative affect which includes depression, anxiety, anger, fear, hostility, and guilt was positively associated with bingeing, laxative use, vomiting, and exercising in both AN and BN (119). Negative affect in women with BN had a positive correlation on fMRI with activity in the putamen, caudate, and pallidum measured during anticipated intake of a palatable food (120). The authors suggested negative affect may increase the reward value of food in BN or be a conditioned cue due to binge

eating in a negative mood.

Set shifting, which involves various cognitive functions, was impaired in 22.9% AN-R, 45.5% AN-BP, 36.7% BN, 16.7% recovered AN, and 9% controls (121). Those with impaired versus those with intact set shifting were twice as likely to have a longer duration of illness, a higher Yale-Brown-Cornell Eating Disorder Scale (YBC-EDS) rituals score, and a diagnosis of social phobia. Two studies have demonstrated the set-shifting deficits do not exist in AN adolescents in contrast to AN adults (122,123). This may be due to not fully developed brain circuits in adolescents.

All eating disorders were found to be sensitive to punishment compared to controls. However, AN-R were least sensitive to reward and had higher levels of behavioral inhibition whereas bulimic types were more sensitive to reward and had higher levels of behavioral activation (124,125). Impaired behavioral response shifting in AN measured by fMRI revealed hypoactivation in the ventral anterior cingulate–striatal–thalamic loop (126). Dopamine and norepinephrine modulate the functioning of the striatal–cortical loops. Since dopamine is active in the ventral–striatal–cortical loop for set shifting and norepinephrine is active in response inhibition and sustained attention, it is reasonable to suggest these monoamines may be involved in initiating and maintaining core eating disorder symptomatology.

Psychiatric disorders comorbid with eating disorders are predominantly in four categories: affective, anxiety, substance use, and personality disorders. According to the National Comorbidity Survey Replication any mood disorder was present in 42.1% of AN, 70% of BN, and 46.4% of BED persons. Any anxiety disorder was present in 47.9% AN, 80.6% BN and 65.1% of BED persons. Any substance use disorder was present in 27% of AN, 36.8% of BN, and 23.3% of BED persons (19). The above figures represent a general pattern and will vary according to the sample studied. In the same survey Impulse Control Disorder was found in 30.8% AN which included both types of AN. Fernandez-Aranda et al. (127) found only 1.7% of restricting AN had this disorder. Impulse control disorder is highly associated with binge eating and is present in 63.3% of BN and 43.3% BED persons (19). Likewise, oppositional and conduct disorders are more prevalent in disorders with binge eating (19). Cluster B, the impulsive personality disorders are almost exclusively associated with binge eating (128).

Comorbid psychological features and psychiatric diagnoses are common in eating disorders and must be incorporated in comprehensive treatment strategies.

FAMILY FACTORS

Family factors influencing the development and maintenance of eating disorders can be parental psychiatric diagnoses, parental practices, and family interaction characteristics. Information of these factors may be obtained by interviews, self-

questionnaires, or observed behavior.

Analyses from the Stockholm Youth Cohort revealed a diagnosis in one or both parents of bipolar affective disorder, anxiety and depression disorders, or a personality disorder was a risk factor for eating disorders in their offspring (129). One study found girls of AN women were more likely to have emotional, conduct, and hyperactive disorders and boys to have emotional disorders compared to offspring of healthy women. In the same study girls of BN women were more likely to show hyperactivity and boys to show emotional and conduct disorders compared to controls (130).

Adolescent self-report on the Family Assessment Device (FAD) found parental psychological control moderated the protective relationship between family functioning and disordered eating behaviors in adolescent girls. Parent psychological control was associated with greater odds of engaging in dieting and disordered eating behaviors while parents knowledge of the child's whereabouts was associated with lower odds of dieting and having disordered eating behavior (131). A study of adolescents in the United Kingdom found for both girls and boys lower perceived parental responsibility for food was significantly related to greater eating psychopathology. For girls pressure to eat and for boys parental restriction of food led to unhealthy eating-related attitudes (132).

A multicenter European project found perceived abusive parenting was related to the development of AN-BP and BN but not AN-R (133). Other studies found perceived family influences such as negative attitudes about weight and shape, promoting dieting, and parental weight loss practices to be associated with disordered eating behavior (134,135). Mothers eating and exercising attitudes predicted their activity-related parenting practices with daughters (more controlling) and sons (136).

A study using the FAD self-report measure found half of AN families experience some impairment of family function. Adolescent's perspective on family function reflected greater family dysfunction compared to parental ratings. Adolescent but not parent ratings of global family function were associated with more severe eating disorder symptoms, greater depression, lower self-efficacy and self-esteem, and more functional impairment. The authors suggested that the adolescent's view of family functioning was more clinically relevant (137).

A direct effect of marital conflict occurring during a child's kindergarten year was found on adolescent disordered eating and was mediated through the child's emotional insecurity about the marital relationship (138). Another study found adolescent reports of the level of family cohesion were more accurate than parent reports in predicting changes in adolescent mental health (139). In a study of BN adolescents, low patient/low parent expressed emotion showed greater reduction in purging overtreatment with high patient/low parent expressed emotion showing smallest reduction in purging (140).

Patients with BED perceived their mothers as high expressed emotion and reported significantly higher levels of perceived maternal criticism, emotional overinvolvement, and lower levels of perceived warmth than did controls (141). Parental perception of family functioning is affected by both the presence of binge eating/purging behavior and nonsuicidal self-injuring behaviors with worse family functioning occurring in the latter group (142).

DIFFERENTIAL DIAGNOSIS

In making a diagnosis of AN it is important to be certain the patient has no medical illness that can account for weight loss. Occasionally, a patient may have both AN and a medical illness contributing to weight loss. In this situation the diagnosis of AN is made by the positive criteria for the disorder, and both the underlying medical condition and the AN are diagnosed and treated as such. Weight loss frequently occurs in depressive disorders. However, in the latter the patient usually has a decreased appetite, whereas an anorectic patient denies the existence of an appetite. The hyperactivity seen in AN differs from the agitated activity seen in depressive disorders in that the anorectic's activity is planned and ritualistic, such as exercising programs of jogging and cycling. The preoccupation with the calorie content of food, collecting recipes, and preparing meals for others is typical of the anorectic patient but not present in those with a depressive disorder. The latter do not have a fear of becoming fat or a disturbance in their body image, as is characteristic in AN.

Delusions about food in schizophrenia are rarely concerned with the calorie content of food. A fear of becoming obese and hyperactivity is also uncommon in the schizophrenic but is typical of the anorectic patient.

Chronic medical illnesses frequently associated with weight loss are Crohn disease, hyperthyroidism, Addison disease, and diabetes mellitus. Overeating episodes may occur in the Kluver–Bucy syndrome, which consists of visual agnosia, compulsive licking and biting, inability to ignore any stimulus, and hypersexuality. Another uncommon syndrome associated with hyperphasia is the Kleine–Levin syndrome, which is characterized by periodic hypersomnia lasting for several weeks.

TREATMENT

Anorexia Nervosa

The British National Institute for Clinical Excellence (NICE) developed a grading scheme for which all treatment was classified according to an accepted hierarchy of evidence (143). A summary of the NICE guidelines for AN is as follows: (1) Patients should be managed on an outpatient basis whenever possible with psychological

treatment given by an experienced and competent service that also assesses physical risks. (2) Inpatient treatment should be in an experienced setting that can implement refeeding with careful physical monitoring and give psychosocial intervention. (3) Family intervention that directly addresses the eating disorder should be offered to children and adolescents.

The above recommendations for treating AN continue to be valid. However, in the past decade more specific evidence-based data have emerged. Meeting the criteria for the highest level of "well established" is family therapy with a behavioral focus often referred to as family-based treatment. This approach which has a manualized published version (144) promotes parental management of weight restoration through education and support by focusing on eating disorder symptoms in the early phase of treatment and emphasizing general family interactions after weight gain is well underway.

Probably, efficacious criteria are applied to family systems therapy and insight-oriented individual psychotherapy referred to as adolescent-focused therapy or ego-oriented individual therapy. Family systems therapy focuses on general systematic and interactive concerns in the family. The therapist adopts a neutral stance, explores family patterns of beliefs and behaviors and seeks ways to enable the family to generate solutions (145). The adolescent-focused therapy, also manualized (146), is based in self-psychology and cognitive individual therapy that targets self-esteem, self-efficacy, and autonomy. Randomized controlled trials (RCTs) have shown family-based (behavioral) therapy to be superior to adolescent-focused therapy (147) and family systems therapy (145). Family behavioral therapy resulted in a faster weight gain, greater recovery rates, and fewer days of hospitalizations during treatment.

Additional analyses of the above studies revealed information moderating treatment. Patients with higher levels of obsessive-compulsive features and those from single parent families had greater improvement with a high dose of therapy. Intact families and those with AN-R adolescents had higher rates of remission regardless of treatment. Adolescents with greater obsessive-compulsive features gained more weight with systems family therapy compared to behavioral family therapy. Other studies have shown that the use of hospitalization solely for the purpose of weight gain may not be useful for most AN adolescents (148).

Exploratory studies are examining the utility of multifamily therapy in both adults and adolescents with eating disorders (149,150).

Family therapy for AN has been predominantly applied to children and adolescents. Other forms of AN individual therapy receiving an experimental level designate and studied mainly in adults are beginning to be tested in adolescents. Cognitive therapy which addresses cognitive inflexibility is considered an adjunctive treatment (151) with the purpose of enhancing quality of life in social, work and health domains (152). Dialectical behavioral therapy (DBT) is another experimental

treatment that targets emotion regulation and is most often used in patients with bingeing and purging behaviors (153).

Weight restoration and nutritional rehabilitation are extremely important since the state of being underweight is associated with depression, difficulty concentrating, irritability, and preoccupation with food. Also, cognitive impairment is present during this state of calorie restriction. In order to accomplish necessary changes with psychotherapy the patient must be in a condition where she can actually concentrate on the issues of psychotherapy. Monitoring is an important part of CBT. In an outpatient setting the patient is taught to record not only her food intake but stressful circumstances during the day and her emotional responses to them. Cognitive restructuring is a method in which patients are taught to identify their disturbing cognitions and challenge their core beliefs. In this process they become aware of specific negative thoughts and present arguments and evidence both to support their validity and to cast doubt on their validity. From this they try to form a reasoned conclusion based on the evidence. Problem solving is another method whereby patients learn to reason through difficult food-related and/or interpersonal situations. Adolescents from age 12 onward are fully capable of participating in this type of therapy.

A family analysis should be done on all anorectic patients who are living with their families. From this analysis a clinical judgement should be made as to what type of family therapy or counseling is clinically advisable. There will be some cases in which family therapy is not possible, and in those instances family relationships can be addressed in individual therapy. In other situations brief counseling sessions with the immediate family members may be the best manner of dealing with family issues. A controlled family therapy study (154) has shown that anorectic patients under the age of 18 benefited from this whereas patients over age 18 did worse in family therapy compared with the control therapy. In another randomized controlled treatment trial 40 adolescent patients with AN were randomly assigned to conjoint family therapy or to separated family therapy with one therapist conducting both forms of treatment. On a global measure of outcome, the two forms of therapy had equivalent end of treatment results. For those patients with high levels of maternal criticism toward the patient the separated family therapy was shown to be superior to the conjoint family therapy (155). In actual practice, many clinicians provide individual therapy and some sort of family counseling in managing AN.

Medication should only be considered as adjunct therapy for AN patients with severe or resistant symptoms. RCTs have been severely compromised with small samples and lack of actual serum drug levels making meta-analyses meaningless. AN individuals are extremely reluctant to take medication even after agreeing to participate in a drug trial. RCTs of typical antipsychotics in AN did not reveal significant results (156). Treatment studies of atypical antipsychotics in AN have produced vaying results. The one study measuring actual serum levels of olanzapine

showed an effect for weight gain over placebo (157). Other RCTs have shown a modest effect on improved AN psychopathology (156). Atypical antipsychotics such as risperidone, quetiapine, amisulpride, and aripiprazole have had little effect on improving core AN symptoms (157).

Antidepressants have not been effective for improving core AN psychopathology and may not effect depression symptoms until AN patients are medically stable with adequate weight gain (158).

Although there is conflicting evidence for zinc promoting weight gain, both the WFSBP and APA recommend zinc supplementation may be useful since it is an essential micronutrient (156).

Using estrogen compounds for treating decreased bone density in adolescents remains controversial. NICE guidelines do not recommend it since estrogen replacement may lead to premature fusion of the epiphyses. One study using physiologic estrogen replacement (159) and another using a combination of dehydroepiandrosterone (DHEA) with estradiol and levonorgestrel (160) found increasing bone density and cortical thickness with these compounds in adolescents and young adults. Early detection of illness and weight restoration with nutritional rehabilitation remain the primary treatment of osteopenia in AN.

There have been several double-blind studies to show that cyproheptadine—especially in high doses, up to 24 mg/day—is effective in facilitating weight gain and reducing depressive symptomatology. This drug has the advantage of very few side effects, which make it attractive for use in emaciated anorectic patients (161).

In the exploratory status of AN treatment are intranasal oxytocin, D-cycloserine facilitation of exposure therapy, repetitive transcranial magnetic stimulation, internet-based interventions (computer or mobile), and for adults with severe intractable AN, deep brain stimulation and stereotactic surgery to inactivate the nucleus accumbens.

Medical management, a necessary part of the treatment of AN patients, is based on the experience of clinicians and not RCTs. Nutritional rehabilitation programs should establish healthy target weights with a weight gain of 2 to 3 lb per week for inpatient and 1 lb per week for outpatient treatment programs. Patients must be monitored for discarding food, vomiting, or exercising frequently. Medical monitoring during refeeding includes assessment of vital signs, food, and fluid intake and output, assessment of electrolytes (including phosphorous), observation for edema, rapid weight gain with fluid overload, congestive heart failure, constipation, and bloating. Physical activity should be adapted to the food intake and energy expenditure of the patient. Liquid food supplements may be very helpful in the initial stages of treatment. Forceful intervention should be considered only when patients are unwilling to cooperate with oral feedings and their physical safety is in danger. Nasal gastric feedings may be required in life-threatening circumstances. During hospitalization the use of liquid formula in the early stages of weight gain with gradual exposure to food and gradual increase in activity can be very effective for

inducing weight gain (162). Specialized eating disorder units yield better outcome than general psychiatric units because of the specific nursing expertise and more effective protocols (163). A study by Watson et al. (163) showed that short-term outcomes for involuntarily hospitalized patients are similar to those voluntarily admitted.

Early detection and treatment of adolescents before adulthood is the best prevention of chronic AN. Family therapy is the first recommended treatment with attention to multifaceted needs such as weight restoration, nutritional rehabilitation, and medical stabilization.

Bulimia Nervosa

CBT is the first-line treatment for (BN). It has been found to be the most effective treatment in over 35 controlled studies. In these studies the treatment program was usually 16 to 20 weeks, after which 40% to 50% of the patients were abstinent from both bingeing and purging. A reduction of bingeing and purging occurred in 70% to 95% of patients. Another 30% of those who did not show improvement immediately after treatment did show improvement to full recovery 1 year after treatment. In BN, CBT interrupts the self-maintaining cycle of bingeing and purging and alters the individual's dysfunctional cognitions and beliefs about food, weight, body image, and overall self-concept. It should be noted that in order for therapists to be effective in using CBT for the treatment of BN, they need to be trained in these specific manuals available for this purpose. Wilson and Fairburn (164) have written an excellent review of these studies.

In the past decade cognitive behavior therapy (CBT) has been modified in recognition that more than half of BN patients receiving CBT do not recover. Enhancements to address perfectionism, mood, interpersonal problems, and low self-esteem were added to the tested CBT and this is referred to as CBT enhanced (CBT-E) (165). Few RCTs exist for treatment of BN in adolescents. CBT adapted for children (CBT-A) and family-based therapy for BN (FBT-BN) were found to be effective for treating adolescent BN (166,167). These therapies have a designated level of possibly efficacious. A more recent RCT found FBT-BN was more efficacious in promoting abstinence from binge eating and purging than CBT-A in adolescent BN at end of treatment and 6 months but no difference was present at the 12-month follow-up (168).

Multifamily therapy for adolescent BN is in the developmental stage (169).

Interpersonal therapy (ITP) which targets specific interpersonal problems associated with eating disorder symptoms is an effective treatment for adults with BN but produces results slower than CBT (170) and has not been studies in BN adolescents. Other treatment strategies being tested for BN include the use of the internet to support self-help and phone messages for behavioral monitoring.

Although group therapy has not been adequately studied in a controlled manner, in practice many clinicians are conducting group CBT for patients with BN. This seems to be especially effective and popular with college students and young adults. Furthermore, it is a cost-effective treatment modality for both patients and therapists.

Over a dozen double-blind, placebo-controlled trials of antidepressants, including desipramine, imipramine, amitriptyline, nortriptyline, phenelzine, and fluoxetine, have been conducted in normal-weight outpatients with BN. The dosage of antidepressant medication used was similar to that used for the treatment of depression. In all trials, antidepressants were significantly more effective than placebo in reducing binge eating. These medications also improved mood and reduced eating disorder symptoms such as preoccupation with shape and weight. However, the abstinence rate from bingeing and purging on the average was only 22%. An excellent review of these studies is available in Mitchell and DeZwaan (171). There is some indication that combining antidepressant medication with CBT is helpful in some individuals (172).

More recently topiramate, an antiepileptic drug associated with appetite suppression and weight loss, was investigated as a treatment for BN in a randomized control trial involving 69 patients treated for 10 weeks. The median dose was 100 mg daily (range 25 to 400 mg daily). Topiramate was more effective than placebo in its effects on binge eating and purging and on measures of psychosocial impairment (173,174).

An analysis from two large fluoxetine trials found BN patients who failed to report a greater than 60% decrease in the frequency of binge eating or vomiting by week 3 of treatment were unlikely to respond to this drug (175). This is a helpful indication to guide clinical management in BN.

Binge Eating Disorder

A large number of RCTs provide evidence that CBT is the most well-established psychological treatment of adults with BED (176,177). CBT produces substantial reduction in binge eating and related symptomatology that is maintained for a long time (178). ITP has also been demonstrated in RCTs to be effective in treating BED (153). Fewer RCTs suggest that DBT and group therapy are promising for treating BED (179).

For adolescents with BED only pilot preliminary RCTs exist. CBT compared with a delayed treatment control was efficacious in producing abstinence from binge eating over a 3-month follow-up in 12- to 18-year-old adolescents (180). An internet-based CBT program reduced binge eating and shape and weight concerns and facilitated weight loss in overweight adolescents over a 5-month follow-up (181). Another RCT of 12- to 17-year-old girls showed group ITP reduced binge eating at 3-month follow-up compared to a standard health education group (182).
